There has been significant interest in laser-based-processing methods for the manufacturing of complex components (e.g. additive manufacturing) or post-processing/repair work (e.g. laser welding). Since laser processing tends to result in the formation of rapidly solidified microstructures, it becomes increasingly important to understand the microstructural development under such non-equilibrium conditions. Pulsed-laser-based-processing methods have been foci of investigations on rapidly solidified microstructures. This method has been shown to produce unique microstructures and micro-constituents in metallic thin films at the nanometer-scale [1].

Recently, in-situ dynamical transmission electron microscopy (DTEM) studies on the rapid solidification of hypo-eutectic Al-Cu alloys have identified a modulation of the microstructural features as a function of solid-liquid interface motion [2]. Elucidating crystallographic dependencies during rapidly solidifying crystal growth in multi-phase alloys systems is of fundamental importance in understanding laser-assisted solidification processes [3-5]. However, due to the nm-scale of the resulting microstructural features, acquiring data sets with the appropriate spatial-resolution is challenging with electron backscatter diffraction (EBSD) based orientation image mapping (OIM) in scanning electron microscopes. A promising alternative analytical technique, which offers nm-spatial resolution, is precession electron diffraction (PED) based automated crystal orientation mapping (ACOM) in the TEM. This technique provides statistically significant and representative data sets for mapping of crystal orientations and spatial distribution of crystalline phases for instance.

Here we report an investigation of the microstructural development in a pulsed-laser melted rapidly solidified thin film alloy of Al-3at. % Cu. Under equilibrium conditions this hypoeutectic Al-alloy contains the face-centered cubic α -Al matrix and tetragonal θ -Al₂Cu precipitate phases. Solid-liquid interface velocities obtained via in-situ DTEM experiments as high as 1.5 m/s are reached during solidification. These high interface velocities produce microstructures that deviate from those expected under more conventional conditions. Figure 1a is a collection of bright field TEM images of a representative melt-pool produced from laser irradiation exhibiting the different morphological zones arising during rapid solidification, e.g. Heat-affected zone, Columnar grain growth, Banded microstructure. Figure 1b is an expanded view of the melt-pool edge region, which shows the columnar growth zone with fine-scale copper rich precipitates, identified as the metastable Al₂Cu (θ') phase. The crystallographic orientation relationships (OR) of Al matrix and precipitates were determined by ACOM (e.g. Figure 2). The Al grains are aligned such that the $\langle 100 \rangle$ direction is parallel to the crystal growth, i.e. solidification, direction. A large proportion of the precipitates adopt an OR of $\{001\}_{\theta'} \parallel \{110\}_{\alpha}$ & $\langle 110 \rangle_{\theta'} \parallel \langle 100 \rangle_{\alpha}$ (Fig. 2b), and the minority adopt the expected 'cube' OR of $\{001\}_{\theta'} \parallel \{100\}_{\alpha}$ & $\langle 100 \rangle_{\theta'} \parallel \langle 100 \rangle_{\alpha}$ (Fig. 2c). However, many precipitates do not exhibit any low-index OR with the Al matrix. The statistically significant analysis shows clearly deviations from the ORs characteristic of

solid-state transformation products for this system, which are strongly affected by interfacial strain energy, implying here that matrix and precipitate crystals formed concomitantly from the liquid.
