Figure 1: We propose a novel Landmark-Aware Visual Navigation (LAVN) dataset for map representation research. LAVN provides unique landmark information (in red) in specific scenes to aid model navigation and exploration performance and map representation learning. In this figure, a human expert in Room A (in blue) provides a video-based training trajectory (in green lines) for navigation given a goal image (green box). Rooms are depicted in different colors and represented with nodes. Our dataset facilitates topological map representation learning by injecting novel landmarks into a robot's observation.

and tasked with finding and reaching it in the environment. The success of state of the art (SOTA) methods at this task comes down to an agent's ability to efficiently explore its environment. Several works focus on explicitly learning optimal exploration policies [\[8–](#page-4-11) [10,](#page-4-12) [41\]](#page-4-13), but this is not the case for the majority of SOTA methods. They either abstract exploration out of the problem all together by assuming that the environment has been seen by the agent prior to test time [\[23\]](#page-4-9), assume that their networks will implicitly learn an adequate exploration strategy from the data due to the specific task structure [\[22\]](#page-4-14), or explicitly define the exploration strategy for the agent by hard coding it into the architecture [\[17\]](#page-4-8).

Of those methods that learn to explore, several niches have arisen such as adding an exploration term to RL reward functions with [\[41\]](#page-4-13) and without [\[12\]](#page-4-15) behavioral cloning, building metric maps or graphs with [\[8\]](#page-4-11) and without [\[11\]](#page-4-16) semantics, and learning to propose exploration waypoints that provide helpful subgoals during navigation for local policies [\[10\]](#page-4-12). These methods suffer from similar downsides as those mentioned previously with the added potential for also requiring full ground truth semantic labels of an environment, which can be extremely costly to acquire. Instead, a much

ABSTRACT

Map representation learned by expert demonstrations has shown promising research value. However, recent advancements in the visual navigation field face challenges due to the lack of human datasets in the real world for efficient supervised representation learning of the environments. We present a Landmark-Aware Visual Navigation (LAVN) dataset to allow for supervised learning of human-centric exploration policies and map building. We collect RGB observation and human point-click pairs as a human annotator explores virtual and real-world environments with the goal of full coverage exploration of the space. The human annotators also provide distinct landmark examples along each trajectory, which we intuit will simplify the task of map or graph building and localization. These human point-clicks serve as direct supervision for waypoint prediction when learning to explore in environments. Our dataset covers a wide spectrum of scenes, including rooms in indoor environments, as well as walkways outdoors. Dataset is available at DOI: 10.5281/zenodo.10608067.

1 INTRODUCTION

Robotic navigation remains a research problem of interest as advances in AI make mobile intelligent agents, such as delivery bots, more feasible. Many approaches have been proposed from SLAM [\[5,](#page-4-0) [24,](#page-4-1) [25\]](#page-4-2), to graph-based methods [\[3,](#page-4-3) [4,](#page-4-4) [18,](#page-4-5) [21\]](#page-4-6), to reinforcement learning (RL) [\[43\]](#page-4-7) to enable robots to effectively move around a space in a goal-oriented manner. However, these methods suffer from high computational complexity, high memory usage, and low sample efficiency respectively. Visual navigation [\[17,](#page-4-8) [23,](#page-4-9) [26\]](#page-4-10) methods circumvent several of these challenges by using neural networks to implicitly learn scene geometry and an optimal navigation policy without necessitating direct environment interaction.

Typically, visual navigation methods are evaluated with the image goal task, where an agent is given a goal image of some target

Table 1: Summary of dataset characteristics for visual navigation. Different from existing datasets, LAVN provides video-based trajectories guided by humans in both simulated and real-world scenarios. We are the only dataset to provide labels for helpful navigational landmarks. These landmarks introduce little overhead to an agent's learning scheme, as they do not necessitate the interpretation of the additional text modality as in VQA, or heavy semantic understanding of the environment. We are also the only dataset to provide human trajectory demonstrations in both real world and simulated environments. While we do not provide millions of data points, we allow for supervised model training, which removes the need for copious amounts of data.

simpler approach would be to explicitly learn good exploration techniques in a human-centric manner. Learning human-centric exploration strategies in a supervised manner would allow for much simpler networks to effectively solve navigation problems, thus reducing the computational complexity, high memory usage, and low sample efficiency issues of SOTA. However, there is very limited data that would allow for this kind of learning.

In this work, we present a Landmark-Aware Visual Navigation $(LAVN)$ dataset^{[1](#page-1-0)} of human-guided environment exploration videos collected from the photo-realistic Habitat virtual environment as well as several real world environments. We collect RGBD image observations and human point click pairs as a human guides an agent in exploring each environment. These point clicks represent subgoals that guide the agent incrementally though the space and can be used for supervised learning of human-centric waypoints for environment exploration. Additionally, we expect that having landmarks when exploring has the potential to improve current SOTA performance on map-building and localization tasks inherent in navigation. To this end, the human annotator also provides examples for helpful navigation landmarks, which also allows for supervised training of landmark prediction networks. In this way, it becomes possible to directly train a network to explore an environment in a human-centric manner under multiple SOTA paradigms.

This paper is organized as follows: we summarize our dataset's key differences from existing works in Section [2.](#page-1-1) Then, we present the details of data acquisition in both the virtual (Section [3\)](#page-1-2) and realworld (Section [4\)](#page-2-0) environments. The details of the dataset format will be described in Section [5.](#page-3-0) We conclude our work in Section [6.](#page-3-1)

2 RELATED WORK

2.1 Map Representation for Navigation

The success of navigation relies on an effective learning and understanding of the environment. Two main approaches for this are map representation learning in geometry-based [\[5,](#page-4-0) [24,](#page-4-1) [25\]](#page-4-2) and learningbased [\[9,](#page-4-21) [23,](#page-4-9) [31,](#page-4-22) [37,](#page-4-23) [43\]](#page-4-7) categories. However, the former requires careful and robust hand-engineered feature design and requires intensive computation (e.g. keyframes in SLAM). The advancements of Deep RL in the second category are partially attributed to the emergence of simulators designed for photorealistic simulation,

including Habitat AI [\[29,](#page-4-24) [35\]](#page-4-25) with datasets Gibson [\[40\]](#page-4-26) and Matterport [\[7\]](#page-4-27). While these simulators enable large scale model training, they are also expensive to build, can run slowly enough to mitigate their ability to produce large numbers of training samples, and introduce the sim2real problem when deploying models in the real world. To combat this, methods like NRNS [\[17\]](#page-4-8) demonstrate the effectiveness of using expert videos to train robots without interacting with environments.

2.2 Human-Robot Interaction Datasets

There is a large body of datasets or benchmarks for Human-Robot Interaction, ranging from industrial [\[19\]](#page-4-28) to social [\[2,](#page-4-29) [13,](#page-4-30) [16,](#page-4-31) [20,](#page-4-32) [28,](#page-4-33) [30,](#page-4-34) [34,](#page-4-35) [38\]](#page-4-36) environments. As one of the fundamental tasks for robots, researchers have collected datasets for learning visual navigation with socially compliant behaviors [\[2,](#page-4-29) [13,](#page-4-30) [16,](#page-4-31) [20,](#page-4-32) [28,](#page-4-33) [30,](#page-4-34) [34\]](#page-4-35). Apart from learning from other robots collectively [\[32\]](#page-4-37), robotic visual navigation can benefit from human feedback via visual cues [\[39\]](#page-4-18), language [\[36\]](#page-4-38), gesture [\[6\]](#page-4-39), multimodal instructions [\[30,](#page-4-34) [33\]](#page-4-40), or demonstrations [\[27\]](#page-4-17).

Our work extends the line of efficient map representation using topological graphs [\[18,](#page-4-5) [21\]](#page-4-6). Similar to how a human [\[14\]](#page-4-41) can quickly learn to navigate in a new environment by implicitly treating landmarks as nodes in their mental graph [\[14\]](#page-4-41), we hypothesize that a robot can acquire the ability to navigate in novel places efficiently by intelligently injecting landmarks into its own topological graph. However, little attention has been paid to such datasets, resulting in a lack of data that includes landmark information for this research in the literature. Our dataset hereby aims to fill this gap by providing a series of human-expert-annotated video with landmarks both in virtual and real-world datasets, including indoor and outdoor scenes. We summarize the key characteristics of recent datasets in Table [1.](#page-1-3)

3 VIRTUAL DATASET

The main objective of the data collection is to provide human navigation demonstrations for robots in a real-world environment. As video has been proven to be an effective way to teach robots to accomplish different tasks [\[17\]](#page-4-8), we hereby collect trajectories in video format. Below, we detail the process of data collection for the virtual dataset.

¹Dataset is available at [https://zenodo.org/records/10608067.](https://zenodo.org/records/10608067)

A Landmark-Aware Visual Navigation Dataset

Figure 2: Samples of RGB images in our dataset captured from an ego-centric camera. Video frames start from left to right. Landmarks are visualized with red dots. Samples in the virtual dataset (1st and 2nd rows in blue) are visually realistic compared to the real-world observations (3rd and 4th rows in green), which makes landmark data acquisition scalable to serve real-world research purposes.

3.1 Environments

We provide human-click annotations for a selection of the Matterport [\[7\]](#page-4-27) and Gibson environments [\[40\]](#page-4-26) in Habitat-Sim [\[29,](#page-4-24) [35\]](#page-4-25) to facilitate virtual environment exploration. We provide a full list of annotated environments with the data. Habitat is already used to train many visual navigation methods, so having in-domain, landmark-aware data will allow for direct extensions of these methods for greater ease of model comparison. Additionally, it allows for greater data collection volume and lower data processing time.

3.2 Data Collection and Representation

To start, the human navigator is placed at a random, navigable point in an environment, and tasked with visiting as many rooms as possible while identifying distinct landmarks in each room. The current first person observation of the environment is shown on a screen, and the human moves through the environment by left clicking on this image towards the direction they would like to move. There are three discrete action choices for moving around in the environment: moving forward 0.25m, turning left 15◦ , and turning right 15°. To specify a landmark, the navigator right clicks on the observation image over the object or region of space they choose. We provide a human point-click supervisory signal for each time step of the trajectory, but these signals could easily be masked to generate data to train temporally abstracted waypoint predictors.

A graph is built as the navigator moves through the space, where nodes are added each time an action is taken. Each node contains one RGB observation, one depth image, the human navigational point click, and the ground truth odometry (including ground truth location and orientation). Edges are drawn between consecutive nodes only, however it is possible to do loop closure on the graph using the odometry provided. Each graph also contains a sequential list of the actions taken to move through the environment. A list of pairs of landmark point-click image coordinates paired and their corresponding nodes is also provided in the graph so that landmarks may be easily identified in the scene. Each human-guided trajectory is terminated after 500 actions or when the annotator has navigated through the entirety of the space, whichever comes first.

4 REAL WORLD DATASET

In this section, we detail the process of data collection for the real-world dataset. We aim to make the data collection and representation steps between the virtual and real-world datasets as similar as possible.

4.1 Environments

Real-world data is recorded in a broad spectrum of environments. Indoor scenes include laboratories and hallways inside a building, while outdoor environments contain avenues, walkways, and campus buildings with different architectures. A wide range of trajectories with various complexities are captured in both regular shapes such as rectangles in corridors inside a building, as well as irregular shapes on roads surrounded by trees or near a lake. Objects in common environments are included, ranging from chairs, desks, doors, and computers in indoor rooms, to trees, lakes, stones, bikes, bricks and so forth in open spaces outside a building.

Figure 3: Samples of RGB images in the real world environments with landmarks annotated by red dots. Trajectories are recorded in comprehensive environments both indoors and outdoors.

4.2 Data Collection and Representation

In order to collect consistent data between the real-world data and simulation, our human annotator is asked to follow the same protocol as they did in the virtual environment described in Section [3.2.](#page-2-1) During navigation, the annotator holds a camera (iPhone13Mini [\[1\]](#page-4-42)'s built-in camera) naturally around 1.5m high off the ground facing forwards. Unlike in simulation where agents can move with exact distances or turning angles, real-world environments require that each action taken by the human navigator is inherently inexact. Therefore, the navigator is instructed to follow the same discrete action choices by its own judgement. Specifically, the expert takes a picture (saved in JPEG) in every step with around 0.7 meters, or in .
every left or right turn in roughly 15°. This also presents real-world data with complex noise or perturbations. Trajectories are recorded in ten diverse scenes in both indoor and outdoor environments shown in Fig. [3.](#page-3-2)

Resolution in the original images was 4032x3024. To promote consistency between the virtual and real-world data, the images are resized to be the same resolution of 640x480 as in the simulation and saved in JPEG format with quality 85%. Landmarks are annotated offline after the videos are saved. Samples from our dataset are visualized in Fig. [2.](#page-2-2) Both virtual and real-world images are photorealistic and can benefit downstream research in the real world. Our proposed dataset provides a unique benchmark for both learning and evaluation to serve the visual navigation community. Our dataset statistics are summarized in Table [2.](#page-3-3)

Table 2: Statistics of our dataset. We detail the number of trajectories, total number of frames per trajectory, landmarks, virtual environments, and real world environments included in the data.

5 FILE FORMATTING

For both datasets, the graph created during navigation is saved as a json file containing edge, action, odometry, point-click, and image path information for each node. The RGB observation and depth images for the virtual dataset are saved as png's of size 480x640. For the real world dataset, the RGB observations and depth images are saved as jpg's of the same size.

The overall file structure of the dataset is separated into different folders for the virtual and realworld datasets. Within the virtual dataset folder, there are different folders for the Gibson and Matterport data, where each trajectory has it's own folder within one of these and is labeled with it's environment name. We provide tools for video playback, reading in the graphs, and processing the images with the data.

6 CONCLUSION

In this work, we introduce a the first Landmark-Aware Visual Navigation (LAVN) dataset with human point-click annotations, providing exploration waypoint and environment landmark labels that allow for supervised training for exploration and map building tasks. We provide trajectories in 300 virtual and real-world environments with RGB observations, depth images, odometry, and human point-clicks for navigation waypoint supervision and environment landmark supervision. With this dataset, it will be possible to create visual navigation models that exhibit human-centric exploration policies to improve model performance on the image-goal task, paving the way for autonomous embodied agents in real-world applications.
